THE ANTIBODY MOLECULE

by A. NISONOFF, J. E. HOPPER, and S. B. SPRING
A Volume in the MONOGRAPHS in IMMUNOLOGY Series

Most of our information concerning details of the properties and structure of the immunoglobulins has been acquired during the past fifteen years. This book summarizes this information and provides over 1200 references to the relevant literature. Perhaps no other book offers such complete and up-to-date descriptions of the immunoglobulins and their properties: the nature of the active site (size, specificity, structure, affinity labeling, reaction rates and equilibria); general properties of human immuno-globulins (IgG, IgM, IgA, IgD, IgE) and those of several other mammalian species; evolution of the immunoglobulins; amino acid sequences, allotypes, idiotypes and their interpretation in terms of the genetic control of antibody diversity; three-dimensional structure of immunoglobulins; interactions of heavy and light chains; and properties of homogeneous antibodies and of myeloma proteins with antibody activity.
1975, 560 pp., $34.50/£16.55

Revised Printing

CHEMICAL AND MOLECULAR BASIS OF NERVE ACTIVITY

by DAVID NACHMANSOHN
with
SUPPLEMENT I
Properties and Function of the Proteins of the Acetylcholine Cycle in Excitable Membranes

This revised edition contains a reprint of the 1959 edition, plus two new supplements. In the first one Dr. Nachmansohn outlines the highlights of the many important new developments in the biochemical investigations of nerve activity — particularly the properties and function of the specific proteins and enzymes associated with the

by DAVID NACHMANSOHN
and
SUPPLEMENT II
Towards a Molecular Model of Bioelectricity
by EBERHARD NEUMANN

action of acetylcholine. Supplement II by Dr. Eberhard Neumann describes in detail an exciting new development, an integral model of nerve excitability. The model integrates many electrophysiological, biochemical and thermodynamic data.
1975, 416 pp., $19.50/£9.35

METABOLISM OF SULFUR COMPOUNDS

Volume 7 of METABOLIC PATHWAYS, Third Edition
editor-in-chief: DAVID M. GREENBERG
CONTENTS: Y. Abiko, Metabolism of Coenzyme A. M. A. Eisenberg, Biotin. I. G. Leder, Thiamine, Biosynthesis and Function. M. Koike and K. Koike, Lipoic Acid. A. Meister, Biochemistry of Glutathione. W. C. Kenney, D. E. Edmond-son, and T. P. Singer, Covalent Adducts of Cysteine and Riboflavin. L. M. Siegel, Biochemistry of the Sulfur Cycle. R. H. De Meio, Sulfate Activation and Transfer. K. S. Dodgson and F. A. Rose, Sulfohydrolases. B. Sörbo, Thiosulfate Sulfurtransferase and Mercaptopyruvate Sulfur-transferase. M. Flavin, Methionine Biosynthesis. D. M. Green-berg, Biosynthesis of Cysteine and Cystine. D. M. Greenberg, Utilization and Dissimilation of Methionine. T. P. Singer, Oxidatve Metabolism of Cysteine and Cystine in Animal Tissues. J. D. Finkelstein, Enzyme Defects in Sulfur Amino Acid Metabolism in Man.
1975, 656 pp., $46.50/£22.30

INSECTS, SCIENCE, AND SOCIETY

(Proceedings of a Symposium on Insects, Science, and Society, held at Cornell University, Ithaca, New York, October 14-15, 1974)
edited by DAVID PIMENTEL
CONTENTS: **Insects and Their Social Implications:** J. J. McKelvey, Jr., Insects and Human Welfare. E. O. Wilson, The Evolutionary Significance of the Social Insects. **Communication among Insects:** R. D. Alexander, Natural Selection and Specialized Chorusing Behaviour in Acoustical Insects. W. L. Roelofs, Insect Communication — Chemical. **Patterns and Processes in Insect Interactions:** J. S. Kennedy, Insect Dispersal. M. D. Pathak, Utilization of Insect-Plant Inter-actions in Pest Control. **Insect Population Dynamics:** T. R. E. Southwood, The Dynamics of Insect Populations. P. S. Messenger, Parasites, Predators, and Population Dynamics. **Insect-Pest Management:** W. Klassen, Pest Management: Organization and Resources for Implementa-tion. L. D. Newsom, Pest Management: Concept to Practice.
1975, 310 pp., $15.00/£7.20

SYSTEMS ANALYSIS AND SIMULATION IN ECOLOGY,
VOLUME 3

edited by BERNARD C. PATTEN

This multi-volume work offers a comprehensive and authoritative picture of applications of systems science and computer technology to ecology. It shows how to model both small- and large-scale environmental systems, and provides numerous examples of applications ranging from dynamics of cell growth in culture to energy and material flows in terrestrial, freshwater, and marine ecosystems.
CONTENTS: **Part I. Ecosystem Modeling in the U.S. Inter-national Biological Program:** J. M. Neuhold, Introduction to Modeling in the Biomes. G. S. Innis, Role of Total Systems Models in the Grassland Biome Study. R. V. O'Neill, Modeling in the Eastern Deciduous Forest Biome. D. W. Goodall, Ecosystem Modeling in the Desert Biome. P. C. Miller, B. D. Collier, and F. L. Bunnell, Development of Ecosystem Modeling in the Tundra Biome. W. S. Overton, The Ecosystem Modeling Approach in the Coniferous Forest Biome. K. E. F. Watt, Critique and Comparison of Biome Ecosystem Modeling. **Part II. Models of Freshwater-Estuarine Ecosystems:** R. G. Wiegert, Simulation Modeling of the Algal-Fly Components of: a Thermal Ecosystem Effects of Spatial Heterogeneity, Time Delays, and Model Condensation. R. H. Boling, Jr., R. C. Petersen, and K. W. Cummins, Ecosystem Modeling for Small Woodland Streams. B. C. Patten, D. A. Egloff, and T. H. Richardson, Total Ecosystem Model for a Cove in Lake Texoma. D. M. Di Toro, et. al., Phytoplankton-Zooplankton-Nutrient Inter-action Model for Western Lake Erie. C. W. Chen and G. T. Orlob, Ecologic Simulation for Aquatic Environments.

Volume 256   July 3, 1975

Guide to authors

● Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.

● Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).

● 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by super-scripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript. All artwork should be marked with the author's name. Line drawings should preferably be in Indian ink on heavy cartridge paper, although other materials are acceptable; thin, shiny, folded, torn or heavily handled material should be avoided. Matt rather than glossy photographs are preferred. Figures are usually reduced to one column width. The originals should be about as wide as a page of *Nature*. Figures, particularly maps, should contain nothing but essential material. It is preferred that the original be unlabelled, but with a copy containing lettering. Labelling on photographs should if possible be avoided entirely. We are always glad to see artwork for possible use on the cover, whether or not it is associated with a manuscript, but cannot guarantee the return of material.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (246, 238; 1973).

Staff changes

This week we say goodbye to two members of the *Nature* staff, John Gribbin and Gillian Boucher.

John Gribbin has been with us for five years, during which time he has made his mark, in particular, as a writer, both in *Nature* and for Nature–Times News Service in *The Times*. He leaves to join the Science Policy Research Unit at the University of Sussex.

Gillian Boucher joined *Nature* two years ago, and for the past year has edited News and Views with considerable distinction. She and her husband will be living in Italy for a year or two.

Extra copies of the chart "Who runs British science?" are available from Subscription Department, Macmillan Journals Ltd, Brunel Road, Basingstoke, Hants, UK. Price 30p (including postage).

Ask the young about the future

THE House of Commons Subcommittee's examination of the future of scientific research in British universities seems in imminent danger of falling apart—not through any violent centrifugal tendencies of its members, but because a growing sense of boredom is beginning to surround its missions. This past week, Sir Sam Edwards, Chairman of the Science Research Council, and Sir Fred Stewart, Chairman of the Advisory Board for the Research Councils, two of the men most central to policy-making in science, dourly defended the present system against some tepid questioning, and once more one wondered why we were all there.

Part of the reason for the lack of enthusiasm is that everyone knows that the education and science sector is suffering heavily from the ravages of inflation, and it is thus no time for reasonable men to start bickering among themselves. And the Rothschild reorganisations are too recent in people's memories for there to be much interest in another round of fundamental changes.

So what can the committee profitably do? It could switch its attention to the young students who are potentially a driving force in science in the 1980s. Two questions about them are surely worth extended investigation. First, are they going to continue to desert the physical sciences in large numbers? And, second, what in the educational system leads to the alienation between pure and applied science, which is an undoubted contributor to Britain's poor performance in converting research into development and production? The committee has shown more than a passing interest in this latter issue and might find it a more congenial question, and certainly one with major economic implications. Fiddling with the dual-support system and the structure of the Science Research Council can at most have marginal benefits in comparison, although a detailed look at the alienation problem might well lead, in the longer term, to the fundamental changes which nobody seems keen to contemplate at present.

Is there money still for tea?

IN recent months, the Department of Energy has been stepping up its campaign to persuade the British public to save energy. "It's everybody's baby. The man who drives alone to work. The boiler-minder who could get more out of his boiler. The housewife who lets her kettle boil away while she chats on the phone. Just by being careful, you can save your own money—and millions for Britain." And in another advertisement a kettle is shown with pound notes steaming out its spout.

Our back-of-the-envelope calculations say this. Britons drink some 2×10^8 cups of tea or coffee daily, of which half come from kettles, each kettle producing two cups, say. Of these 5×10^7 kettles, perhaps half have whistles or automatic cut-outs. Further, of the remainder only about 10% are kept boiling for any substantial period—let us say on average one minute. Thus British kettles boil unnecessarily for 2.5×10^6 minutes daily. This wastes roughly 10^5 kilowatt-hours of energy every day. This costs the foolish housewives of Britain £1,500 a day or an average of 0.015p per family.

Hardly pounds streaming out of each kettle, you may say, but worth saving nevertheless. But it costs money and it uses up energy to run a publicity campaign. Advertisers measure success at the fractions of a percent level—a campaign that persuaded 1% of the population to change its ways would

have been remarkably successful. At stake are thus only 10^3 kilowatt-hours of energy or the colossal sum of £15 a day—although the steam heats up the room and thus for at least half of the year might be deemed a good thing.

We haven't dared ask the department how much this particular advertisement has cost but it must be several thousand pounds—and in the process energy has been consumed in printing it, distributing it and raising it on to a placard.

Ironically, really worthwhile rather than trifling savings are possible when boiling a kettle. Few measure the water into the kettle and as a result an enormous amount of water is raised to the boil and then not used. It is left as an exercise for the reader to determine how much the department could have saved—then to devise an appropriate slogan.

Similar arguments can also be applied to domestic hot-water systems. Lagging a hot-water tank is fine, and the Department of Energy rightly points out that considerable savings of money and energy can be made in this way, but how many people heat their domestic hot water for un-necessarily long periods in the summer, and indeed how many people have hot-water tanks that are too big for their requirements?

international news

Exit Dixy, with acrimony

by Colin Norman, Washington

DR Dixy Lee Ray, the controversial and widely-respected former chairman of the Atomic Energy Commission (AEC) last week quit her job as the top science official in the State Department because she had been virtually frozen out of foreign policy decisions, even on matters involving research and development. Her letter of resignation to President Ford, which she subsequently made public, also contained a sharp attack on the Administration's domestic science policies, suggesting that "pitifully little is being done" in several critical areas, including the setting of policy for energy research and development.

Ray's appointment to the State Department job was widely regarded as a sign that the department's science and technology bureau would be elevated to an important position in the departmental hierarchy. But, after five months of being ignored, she handed in her notice on June 20, and aired her grievances in a series of television interviews and in an appearance before a Senate subcommittee. Her complaints paint a stark portrait of bureaucratic warfare in the State Department, and a gloomy picture of the manner in which foreign policy involving science and technology is made.

Appointed chairman of the Atomic Energy Commission by former President Nixon in 1973, Ray's appearance in Washington was greeted with reams of prose concerning her "sensible" clothes, her knee socks, her two dogs which shared her office, and her motorized home in which she lived close by the AEC's headquarters. In a lacklustre Administration, she stood out as a colourful character, but she also quickly established a solid reputation as a forceful administrator of one of the most controversial agencies in the federal government. She forced the resignation of several AEC officials, made the agency much more open and responsive to public concerns, and adopted a tough, no-nonsense approach in her dealings with other agencies and with Congress.

When the AEC was abolished by an

Dixy Lee Ray: gone but not forgotten

Act of Congress which established the Energy Research and Development Administration and the Nuclear Regulatory Commission, Ray accepted the job as head of a new bureau in the State Department, with the cumbersome title of Bureau for Oceans and International Environmental and Scientific Affairs (OES). The Bureau was foisted on the State Department by Congress, in a bill passed in 1973, but which was not put into effect by the department for more than a year—a fact which indicated the importance which Secretary of State Henry Kissinger attached to the matter. The new bureau is an amalgamation of several former offices; it was supposed to inject high-level analysis into policies concerning science and technology—such as export of nuclear materials, the world food shortage, ocean research and so on.

Kissinger is, however, well-known for ignoring the State Department's bureaucratic machinery in formulating foreign policies, and relying instead on advice from a few key associates. Ray was never one of those associates, and she said last week that by the time her bureau became involved, policies were already established. The bureau, for

example, played no role in negotiations concerning the controversial agreement between West Germany and Brazil on the sale of nuclear materials, matters concerned with the Law of the Sea Conference are handled by another office, and the prime focus of energy policymaking in the State Department is in the Office of Economic and Business Affairs, which is headed by Thomas O. Enders, a close associate of Kissinger's.

In her letter to Kissinger, Ray said that "for some time I had hoped that my office and the Bureau I head would play a significant role in the formulation of the Department's science policy . . . unfortunately, that desirable condition has not been fulfilled. Many of the areas for which OES has statutory responsibility are, in fact, being pursued in other bureaux and offices." Ray subsequently told the Senate subcommittee on oceans and international environment, which was chiefly responsible for the bill establishing OES, that she hadn't seen Kissinger once since she was appointed. She had asked for a meeting to discuss her concerns, she said, but was told to prepare a "briefing paper" instead.

In a longer letter to President Ford,

Ray said "the (OES) Bureau can do little but acquiesce in the policies set by others, and attempt to implement its broad responsibilities with little authority and few resources". She added that "similar problems plague our Nation's domestic science policy ... I am deeply concerned that the imperative to use existing and proven technology for vigorous attack on today's problems is not fully recognised nor appreciated at the highest levels of government."

Ray went on to point out "pitifully little is being done" in the area of energy resources and technology. "Our country is drifting", she said, "we seem neither to have the will to conserve energy nor the courage to map out a national program that will free us from the bondage of too great a reliance on imported energy".

After delivering herself of her grievances, Ray departed last Friday to her native Washington State in her motor home, to complete a book aptly titled "Good-bye America". Washington DC will miss her.

● SUMMER has settled in on Washington, bringing with it mind-boggling allegations of wrongdoings by the CIA, utter indecision in Congress over energy policy, growing speculation about next year's presidential elections, and a smog level officially deemed hazardous to health. Against that background, the mixed political fortunes of the National Science Foundation (NSF) haven't been accorded much attention by the daily press, but last week the House of Representatives took a couple of significant votes on NSF's activities.

The House approved an appropriations bill which would slash $44.3 million from the Ford Administration's proposed budget for NSF for the financial year which began on July 1, ensure that basic research would bear the brunt of that cut, and stop the foundation promoting the use of school science courses. The bill now goes to the Senate, where its prospects are uncertain, but whatever the Senate decides, the hostility toward NSF so far demonstrated by the House is cause for some concern.

The prohibition against promoting school science courses is particularly noteworthy. The NSF has for years been developing innovative school science curricula, which it has promoted by sponsoring courses for teachers to acquaint them with the new materials. But this practice ran into right-wing criticism in the House earlier this year over an NSF-sponsored course called MACOS (Man: A Course of Study). That criticism, in fact, led to many of NSF's other political problems.

Briefly, a number of conservatives in the House attacked MACOS because it depicts the rough realities of Eskimo life rather explicitly in a number of films and books. The leading critic, Representative John B. Conlan, a Republican from Arizona, has described the course as undermining traditional American values, and he objected to the fact that NSF was promoting it against other, privately developed, courses. Conlan proposed an amendment to an NSF bill in April to stop NSF promoting school science courses because, he said, such activities are leading government control of the content of local education. His amendment was narrowly defeated, but the furore which ensued led the House Committee on Science and Technology, and the National Science Foundation itself, to conduct a thorough review of NSF's education programmes.
In spite of the fact that Conlan's amendment was defeated, the House Appropriations Committee approved a budget bill for the foundation on June 20 which expressly forbids NSF from spending any money on promoting school science courses. The committee noted that MACOS is now being taught in 1700 schools throughout the United States, and suggested that use of government funding for promoting particular courses gives them an unfair market advantage. The House adopted the committee's recommendation with scarcely any debate.

The irony in all this is that Congress has in the past been critical of NSF for doing too little to implement the courses, research findings and so on, which result from activities it has funded. Moreover, many educators have pointed out that school science education was in a mess before NSF arrived on the scene.

As for other parts of the NSF appropriations bill, the House decided that NSF should have $727 million to spend in the 1976 fiscal year (including $20 million in funds carried over from 1975), which is $44.3 million less than the Administration requested. The House, moreover, suggested that $35 million of the cut should be taken from the budget proposed for research grants. If accepted by the Senate, the bill would provide a total of $345 million for research grant support, which is an increase of only $5 million over last year's level. The House Appropriations Committee, which recommended the reduction, said that this was a

proper level of funding to maintain.

● The second significant vote on NSF taken by the House last week could, however, provide some relief for that beleaguered agency. A House-Senate conference committee was appointed to decide the fate of, among other things, the so-called Bauman amendment to give Congress power to veto individual NSF grants before they are awarded. The amendment had been attached to the House version of the NSF authorisation bill, but it was not approved by the Senate. When the conference committee was appointed, the amendment's sponsor, Robert Bauman, a Republican from Maryland, proposed a resolution instructing House members of the conference committee to ensure that the amendment is written into the final version of the bill. The resolution was defeated by 127 votes to 284, and it is now considered likely that the Conference Committee will water down the amendment.

● The trouble-plagued liquid metal fast breeder reactor (LMFBR) programme, which is the costliest energy research and development effort in the United States, survived a crucial test in Congress last month. A move to delay construction of the proposed LMFBR demonstration plant for 18 months, while the entire programme is evaluated, was defeated in the House of Representatives by a wide margin—136 votes to 227. A similar move is likely to take place in the Senate next week.

The challenge to the breeder programme came during a debate on a budget bill for the Energy Research and Development Administration. An amendment to delete funds for the demonstration plant and to prohibit ERDA from buying capital equipment for it, was proposed by Representative Lawrence Coughlin, a Republican from Pennsylvania, who argued that the programme should be postponed until it is determined whether or not the breeder is needed. The National Academy of Sciences is among the organisations which is looking into the LMFBR programme.

Although the amendment was heavily defeated, opponents of the LMFBR programme are not too despondent. A year ago, they point out, such a move would probably have gathered only a handful of votes, but unease over some aspects of the LMFBR programme, including its projected cost of $10.7 billion, caused nearly a third of the House to vote in-favour of a delay. It is, nevertheless, generally agreed that this is the critical year for the LMFBR programme. If Congress now sanctions large expenditures on the LMFBR demonstration plant, that investment will make it difficult to turn the programme off in later years. □

A CONTEMPORARY odyssey of pain, repression and, finally, of achievement, reached its climax this week at a ceremony on the Mount Scopus campus of Jerusalem's Hebrew University, in which an outstanding 26-year-old mathematician was awarded a PhD and the prestigious Aharon Katzir Prize. It began six years ago in the town square of Riga, Latvia, where that same young man, Ilya Rips, set himself on fire in order to dramatise his opposition to the Red Army invasion of Czechoslovakia and to Soviet anti-Semitism. Fortunately, passers-by snuffed out the flames and rushed him to a hospital.

Rips was subsequently sent to join other dissidents at a mental institution, where he spent over two years "under treatment". Had it not been for wave after wave of international protests, he would probably still be there From the time he arrived here in January 1972, until this week, Rips—a naturally very reticent person—stayed out of the headlines. He was content to learn Hebrew, which he now speaks with great fluency, and then to immerse himself once again in the world of mathematics, where his work on the dimensional sub-group problem, begun in Riga, has already aroused international interest. Now he is to be a lecturer in the Hebrew University's Mathematics Department.

● Dozens of government personalities were at the Hebrew University ceremony, but few of them have any idea what is really going on in the lecture rooms and laboratories of local institutions of higher learning. Alarmed at the possible consequences of this situation, Israel's academic centres have taken it upon themselves "to educate" the country's policy-making elite. At the Weizmann Institute alone, day-long seminars on various aspects of science have recently been held for members of the Knesset (Israel's Parliament) and for senior officials of the Ministries of Finance, Commerce and Industry, Foreign Affairs and Education. Although the participants sometimes seem to be slightly bewildered by talk about polymers, antigens and quarks, they generally manage to retain their perspective. For example, when a Weizmann Institute official greeted a group of Finance Ministry officials, he earnestly explained to them that the seminar was strictly educational in character and was not being held "to sell you the institute".

"Don't worry," a Finance Ministry man replied, "we don't have the money to buy it. But perhaps you'll give us an option on the place."

● Government monetary limitations notwithstanding, official bodies are putting more money into the development of solar energy, which, as Minister of Commerce and Industry Haim Bar-Lev recently stated, they hope will give the country increased 'economic energy'.

Twenty years ago Israel was in the forefront of solar energy research, but interest in the subject rapidly declined here, as elsewhere, when low petroleum prices seemed to obviate any need for what was then a much more expensive form of energy. Nevertheless, Israel is probably at present the world's largest

Letter from Israel
from Nechemia Meyers

user, per capita, of applied solar energy.

Backing up this contention in a paper presented at a recent solar energy conference in Rehovot, Dr Harry Tabor pointed out that:

(1) The Dead Sea Works, with approximately 100 km² of evaporation ponds, use solar heat equivalent to about 30×10^6 tons of fuel oil per year —three times Israel's annual national consumption.

(2) Over 100,000 domestic water heaters (which save about 100,000 tons of fuel oil that would otherwise be required for heating water) represent about 0.1 m² of flat-plate solar collector per capita.

Tabor sees justification for using solar energy more widely to heat water, to heat and cool buildings and even to provide a power source for desalination. He argues that if solar ponds could be built for less than $10 per m² —which seems feasible—it would be cheaper to use solar energy for desalination than fuel costing $80 a ton.

● Whatever may be the value of Israeli solar energy research, local agricultural research proves its economic significance year after year. Just recently, for example, scientists at the Hebrew University's Faculty of Agriculture reported on the development of new techniques which should facilitate overseas sales of two important export crops—citrus and flowers.

Confronted with the fact that oranges grown north or south of Israel's traditional Coastal Plain citrus belt tend to have rough peels, which makes them unsaleable in Europe, Shaul Monselise, Raphael Goren and Yair Erner, of the Hebrew University, found a way 'to smooth the peels' with a synthetic growth retardant.

Peel roughness is caused by excess levels of gibberellic acid and cytokinins, hormones which control cell division and cell enlargement in the oranges (as they do in other plants). Since there is an excess of these growth regulators in the early stages of the fruit's growth, the team found that peel roughness could be controlled by spraying Alar (a growth retardant) on the citrus during that period. This cut down roughness by 30% without affecting the fruit's nutritional value or making it unsafe to eat. Now equal sucess is being achieved with a less expensive chemical (CCC).

● Israeli agricultural research is distinguished not only by its quality, but also by the fact that it reaches the farmers and the fields much more quickly than it would in other countries, even those with well organised extension services. This is partly because one-third of Israel's agricultural students are themselves settlement members, who rush back home with any promising new hybrid or hormone. In addition, local farmers are not content to wait quietly for solutions to their problems; instead, they keep pestering the professors for assistance and, moreover, they are willing to try innovative methods even when they are still experimental.

Agricultural know-how reaches Arab farmers almost as quickly as it reaches the members of Jewish settlements The 17 Arab students at present enrolled at the Hebrew University's Faculty of Agriculture, as well as Arab graduates, bring new methods to their home villages (inside the country's 1967 borders) and to the West Bank and the Gaza Strip. Production has risen spectacularly in these latter areas since Israeli troops, closely followed by Israeli agricultural advisers, entered them eight years ago.

This rapid transfer of new forms of cultivation, new seeds, new fertilisers and new pesticides could pose a problem for Jewish farmers, because it deprives them of the technological advantage which they would otherwise have over Arab farmers. Indeed, certain crops that were once grown mainly by Jewish farmers, such as strawberries, have been taken over almost completely by Arab farmers, who have access to the same agricultural research and, at the same time, spend less on manpower because their own large families provide a bountiful source of practically free labour.

Yet the Dean of the Hebrew University's Agricultural Faculty, Professor Isaac Harpaz, is not unduly worried. He points out that the economies of Israel and the Administered Areas are closely linked, and likely to remain so whatever form of political settlement is eventually achieved Thus prosperity for Arab farmers benefits the entire economy.

THERE is a good deal of confusion at the Pasteur where a lively campaign is being waged, by means of handbills, rumours and articles in the press, against the genetic manipulation experiments which have just started there.

The story begins a year ago; indeed when the Asilomar Conference of February 1975 gave the go-ahead to the genetic manipulation experiments which had been temporarily halted, French biologists who wished to do similar research were hardly taken unawares. As early as November 1974, they had asked first the CNRS and then the Délégation Générale à la Recherche Scientifique et Technique to set up an organisation to exercise some form of control over research which nobody denies could possibly be dangerous. Two committees were formed; one, with the task of ruling on the ethical problems arising from the experiments, was chaired by J. Bernard, who is Director of the Research Institute for Diseases of the Blood in Paris. It is made up of J. Monod, F. Jacob, F. Gros, R. Monier, J. P. Ebel, Y. A. Chabert and P. Slonimsky.

The other is a committee of experts comprising 15 researchers, doctors and biologists. With the final document of the Asilomar conference as a guideline, they defined the safety limits to which the experiments submitted to them must conform. The parent organisation (CNRS, INSERM, etc) would then be responsible for the effective control of the experiments. In this way, for example, a subcommission on hygiene and safety will soon be set up at the Pasteur.

Asilomar and the Pasteur Institute

from the staff of La Recherche

At the same time, the DGRST gave a grant of 300,000F to build a laboratory to house 'the moderate risk' experiments in the Pasteur. It was there that the so called 'low risk' experiments were initiated—those which had not been delayed in order to wait the Asilomar conclusions; and it was there that the 'moderate risk' experiments were to be started which could result in new vaccines.

The internal meetings at the Pasteur were to inform the whole staff, both researchers and technicians, of the results of the Asilomar conference and of the experiments which were to be carried out.

Nobody expected the explosion which followed these meetings, the first of which had taken place in April. One group of research workers and technicians undertook to fight both the decision to place the special laboratory within the department of molecular biology and also the experiments themselves. An atmosphere of panic overran the Pasteur. Institute biologists and others formed themselves into a 'biological-information group' and recently they have published a manifesto demanding the suspension of experiments and a public meeting where the advantages and disadvantages of the experiments could be debated.

The dissenting movement is very large. It has to be seen within the political and philosophical framework which brings into question genetic manipulation as well as other biological research, virology, genetics etc., where the dangers must be weighed against expected benefits. The movement contests the present reliance on the scientific expert. It questions the way in which science is run, both at the Pasteur, and in general. And finally it poses the problem for whom is science done, scientist or people?

A NUMBER of choices and decisions must be taken this month and next to rationalise international effort on energy research and development, which, otherwise, promises to be a farce or to duplicate what is being pursued nationally in several places. Perhaps the most significant of these moves is the one Dr Walter Marshall, Chief Scientist at Britain's Department of Energy (and Director of Harwell) claims as his personal responsibility. This is a procedure available within the 1974 Kissinger-initiated International Energy Agency (IEA) for developing commercially valuable products on a consortium basis and for protecting these by licencing.

Marshall points out that it is easy to collaborate internationally on basic research and on the exchange of results, but very difficult to do work of commercial value where governments are involved, particularly the US government. This is first, because of the difficulty of interlocking government management, industry and government laboratories. International schemes which involve the US federal government, for example, fall foul of the American system whereby all information derived through federal participation must be freely shared with American industry. Some months ago Marshall successfully argued that commercial undertakings should be in-

Marshalling our power

from Angela Croome

cluded in the agency's programme and that industrial protection was needed for non-American industrial participants.

Only 10 days ago a compromise agreement was reached after several midnight sessions and this has been recommended to the British government for endorsement. It provides a means of setting up industrial consortia with defined objectives and the production of industrial 'products' for licencing. Member countries of the IEA can opt out of any of them. When the product has emerged the countries which had not chosen to join in that particular project would have either to buy a licence to manufacture or make a down payment later.

Nine research themes for the IEA have been chosen so far, including coal, energy from municipal and industrial waste, radioactive waste management, fusion use of waste heat, energy conservation, solar energy, hydrogen conversion and nuclear safety. The concept of the 'lead country' is, in the main, being adopted in the organisation of the work, existing investment and effort being the leadership criteria.

Of the programmes already well developed, for example, fusion work is likely to be led from within the EEC but application is still too far off for a commercial consortium to be needed.

Britain may well take the leadership on coal utilisation research and the fluidised bed development has now reached the consortium stage. Britain has also put money into its own radioactive waste programme so would be expected to participate in the agency's.

Many of the IEA themes are duplicated under the EEC's joint programme, but the organisation and decision-making structure of the latter is very different. The requirement that all EEC decisions have to be unanimous results in decisions being political rather than scientifically based. Whatever may the point of view of the advisers of other EEC countries, Marshall expects to get better value out of the IEA. The budget for Europe's Joint Research Centre is still under review, though expected to be settled this month, and there is every likelihood that most of the proposed programme will be adopted and for this there are obligatory contributions. For EEC members such as Britain, therefore, it seems logical for the IEA to subsume many of the same programmes. By routeing participation through the EEC, member countries should avoid paying twice. □

Weather wise

from Vera Rich

THE recent talks in Geneva between Soviet and US delegations on the banning of climatic manipulation for military purposes has focused attention, once again, on the draft convention dealing with weather warfare which the Soviet Union presented to the United Nations last autumn, and which, at the time, was viewed in many quarters as little more than a kind of appendix to a general concern with problems of the environment.

Russia has, of course, a long history of climatic warfare, and her secret allies 'General January' and 'Field-Marshal February' have, through the ages, proved the downfall of Swedes, Poles, French and Germans. In a situation of conventional warfare, the Russian army has only to retreat sufficiently far and sufficiently slowly for the invader to be trapped by winter —and the climate does the rest. But, endowed as she is with a natural strategic weather advantage, the Soviet Union has been quick to see the possibilities of artificial climatic manipulation. Recent articles in *Mezhdunarodmaya Zhizn'* and *Krasnaya Zvezda* have drawn attention to a number of possible artificial meteorological weapons, ranging from the melting of the Arctic ice and tsunami (tidal waves) caused by nuclear explosions on the edge of the continental shelf to the use of infrasound and atmospheric activity to produce psychotropic effects—depression, terror, and the "suppression of mental activity"—in large groups of the enemy in specific target areas. According to the articles in *Mezhdunarodmaya Zhizn'*, the Americans are researching the possibility of "changing the nature of lightning", with a view to being able to direct electrical charges of "tremendous" power against specific targets.

It would be interesting to know the source of this last piece of information. When Academician Kirillin, the Soviet Minister of Power, visited Britain in May 1974, he was shown an impressive experiment at the Culham Atomic Energy Research Establishment in which lightning striking an aircraft in flight was simulated. Could this have been interpreted as a front for some sinister NATO—and therefore, in Soviet eyes, American—weapon?

Some of the other potential weapons detailed in the Soviet press verge on the fantastic—a localised window in the ozone layer to admit ultraviolet radiation, for example—and it seems difficult to see why Mr Brezhnev has found it necessary to stress the urgency of new agreements banning development in this field. Perhaps the urgency is more a matter of politics than immediate military danger. As a preliminary to the projected Ford–Brezhnev summit meeting, it would be gratifying if the USA and the USSR could reach some form of international agreement in the cause of peace and friendship. And what could be easier than for both sides to renounce the use of a weapon that neither actually possesses at the present time. □

THEOLOGY was once known as "the queen of the sciences", and although an examination of recent *Nature* indexes does not produce many references to this subject, I think it may be permissible to mention the idea of the "God of the gaps". I have unfortunately been unable to trace the origin of this phrase, which is used to describe the views of those who are unable to come out clearly as rationalistic atheists. They hang on to the idea of a deity, but restrict his activities to the gaps between the major fields of man's activities, where science is thought to be able to give a full explanation.

My interest in this theological proposition was aroused when I realised that it was very similar to the view held by many leading conservationists. They say that they believe that wildlife and countryside preservation is important, but they acknowledge that the interests of the farmer and of food production must have priority in any scheme for managing the rural landscape. This point is explicit in the recent report of the Countryside Commission, *New Agricultural Landscapes*. Any wish to retain the familiar pattern of hedgerows, picturesque buildings and flower-rich though rather unproductive meadows is castigated as sentimental. We are urged to try to make the best of the inevitable.

It must be admitted that, even within this pattern of farming development, useful compromises which have done much to spare wildlife (particularly birds) have been possible. There have now been many 'Silsoe-type' exercises, for example. These follow the pattern

Don't ditch hedging

KENNETH MELLANBY

of the first weekend conference at Silsoe in Bedfordshire, when agriculturalists and conservationists tried to work out various schemes for managing a farm where nearly maximum productivity could be married with the least damage to the native flora and fauna. Small, unproductive patches on the farm are identified, and these are planted with trees and shrubs to act as mini-nature reserves.

All these developments result, however, in some impoverishment of the landscape and a reduction in numbers of many native plants and animals. This is accepted because of the belief that we must do everything possible to maximise food production, as otherwise we may all face malnutrition at the best and mass starvation at the worst.

A country like Britain that imports nearly half its food cannot enjoy the luxury of 'wasting' any area for conservation if it can be used for food production.

I believe that the time has come for conservationists to be much more aggressive. Farmers have a right to make a reasonably good living from what may be a very difficult and exhausting job. The government has the duty to see that Britain's food supply is safeguarded, even if the pound sterling falls in value so that we cannot continue to import so much of what we eat. There is a good chance that in a few years the growing world population will absorb any surpluses, and that we will be unable to make good food deficiencies by imports. All these points are taken as arguments in favour of maximising productivity and treating conservation with caution.

I do not believe, however, that the choice is really between the risk of starvation with a rich and varied countryside, and enough food with an impoverished landscape. Britain already produces enough food to provide its population with an adequate diet, with enough calories and protein for all. Imports are mainly used to feed livestock to provide meat, which is produced for enjoyment rather than to prevent any malnutrition. The choice is really between two forms of enjoyment —a meat-rich diet or a countryside rich in wildlife. So the conservationist need no longer be content with the gaps—he can come out in to the open and rightly demand his share in shaping the future pattern of all parts of the rural landscape.

Viruses and histocompatibility antigens: an unexpected interaction

from E. Lennox

IN the minds and activities of immunologists and immunogeneticists those highly polymorphic cell membrane proteins, the major histocompatibility antigens, loom large. These proteins and the products of other genes closely linked to the ones that specify them dominate a wide range of immunological phenomena, among them reactions to tissue transplanted from one individual to another and reactions in culture of mixtures of lymphocytes from different individuals.

In fact thymus-derived cells in particular seem to react strongly and with high frequency to histocompatibility antigens of other members of the species (for example Howard and Wilson, *J. exp. Med.*, **140**, 660; 1974), and even to those of other species (Lindahl and Bach, *Nature*, **254**, 607; 1975). But transplantation and the mixing of lymphocytes in culture are devices of the experimentalist. To what natural phenomena do they correspond? How would the cells of one individual know the histocompatibility antigens of another? Explanations have been sought in phenomena that do lead to cell mixing: fertilisation and gestation (in mammals, at least), sorting during differentiation, transmission of cancer cells (see Bodmer, *Nature*, **237**, 139; 1972; Burnet, *Nature*, **245**, 359; 1973) but none have rung the bell of general acceptance. In fact it can be argued (for example, Cohn, in *Genetic Control of Immune Responsiveness*, edit. by McDevitt and Landy, 427; Academic, New York and London, 1972, and Lafferty and Cunningham, *Aust. J. exp. Biol. med. Sci.*, **53**, 27, 1975) that the apparent importance of the major histocompatibility antigens is exaggerated by the peculiar relation to the immune response and that other polymorphisms are probably equally important.

Now, a new element has been added: in an infected animal, virus-infected cells are vigorously attacked by thymus-derived lymphocytes and the antigen they see is a major histocompatibility antigen modified in a way specific to each virus. Since, moreover, viruses do travel from one individual to another, it is natural to seek an explanation for histocompatibility antigen polymorphism in terms of this remarkable phenomenon (Doherty and Zinkernagel, this issue of *Nature*, page 50).

In their first reported experiments with lymphocytic choriomeningitis (LCM) virus (Zinkernagel and Doherty, *Nature*, **248**, 701; 1974) injected into mice of different histocompatibility types (*H-2* type) they detected cytotoxic T lymphocytes that would kill only LCM-infected cells of the same *H-2* type as the donor of the cytofoxic lymphocytes. This suggested two possible explanations: either cytotoxic lymphocytes, in order to kill, had to match their *H-2* with that of the target or the antigen to which the lymphocytes were sensitised is a virus-induced modification of the histocompatibility antigen of the cell target. Experiments by them and others indicate that the latter is the more likely.

About the same time Blanden (in *Progress in Immunology*, **2**, vol. 4, edit. by Brent and Holborow, 117; Associated Scientific, Amsterdam and New York, 1974; and Gardner, Bowern and Blanden, *Eur. J. Immun.*, **5**, 122; 1975) reported similar findings with ectromelia virus in mice and had shown earlier that the new antigen produced by LCM and by ectromelia in cells of the same histotype were distinct. The total lack of relationship between LCM and ectromelia makes their similar effects on H-2 antigens even more striking. Further experiments have defined more precisely the requirements for *H-2* matching of the virus-infected generator of cytotoxic lymphocytes and of the target (Blanden *et al.*, *Nature*, **254**, 269; 1975).

By using mice of strains with recombinant *H-2* haplotypes on the same genetic background, they were able to show for LCM- and ectromelia-infected mice that *K* or *D* end matching of the generator of the cytotoxic lymphocytes and of the virus-infected target sufficed. This confirmed their previous findings that *M* locus and minor histocompatibility differences were unimportant. Of special interest was the observation that matching of the *I* region (the region of the immune response genes and of the I antigens) was not essential but may exert a minor effect. This tends to emphasise a different kind of mechanism than the *H-2* region matching required for T cell help of B cells for in this case *I* region matching is necessary (Katz *et al.*, *J. exp. Med.*, **141**, 263; 1975).

There have been attempts to elucidate the mechanisms by which viral infection generates a new specificity that depends on the particular virus and the haplotype of the infected cell. Experiments on a seemingly unrelated system provide clues. Shearer (*Eur. J. Immun.*, **4**, 527; 1974) had shown that coupling of the trinitrophenyl group (TNP) to the surface of spleen cells made them good inducers of cytotoxic lymphocytes when cultured with spleen of syngenic mice. Moreover, the major cytotoxicity was directed not at TNP itself (see also Dennert, *Nature*, **255**, 712; 1975), but at the histocompatibility antigen, modified by reaction with TNP. In the virus-infected cell one might imagine an interaction of H-2 protein with viral protein to induce appearance of previously unrevealed determinants in a way that is specific for the H-2 protein and the viral protein.

In favour of this mechanism are several observations. First, the amount of normal H-2 on ectromelia-infected cells seems reduced, for they are less sensitive to killing by lymphocytes specific for their unmodified H-2 (Gardner *et al.*, *Eur. J. Immun.*, **5**, 122; 1975). Second, with vaccinia-infected cells and cytotoxic lymphocytes from vaccinia-infected mice, anti-H-2 serum acting on the target will block cytotoxicity (Koszinowski and Ertl, *Nature*, **255**, 552; 1975). Needless to say, similar H-2 matching of the generators of cytotoxic lymphocytes and of target cells are required as for LCM and ectromelia (Koszinowski and Thomssen, *Eur. J. Immun.*, **5**, 245; 1975). In addition, Koszinowksi and Ertl show that anti-vaccinia serum, not cross reacting with H-2, also blocks. Finally, the amount of H-2, measured by absorption, is reduced on infected cells and preincubation of them with anti-H-2 reduced the amount of anti-vaccinia that could bind. All this

indicates a close physical relationship between H-2 and the viral protein that might induce the H-2 protein to reveal new determinants and hide old ones.

Now we are back full circle. What can all this have to do with histocompatibility antigen polymorphism? Doherty and Zinkernagel (page 50) attempt to tie it to a mechanism for enhanced resistance to viruses. They suggest that the assured heterozygosity at the two ends of the *H-2* locus in a random breeding population gives the virus four different proteins to modify, two at the *K* end and two at the *D* end. This would induce a more vigorous immune response. In support of this they compare the lytic activity of lymphocytes of LCM-infected CBA mice (H-2^x) on cells of:

$$\text{type 1:} \quad \frac{K^x D^x}{K^x D^x};$$

$$\text{type 2:} \quad \frac{K^x D^x}{K^b D^b};$$

$$\text{type 3:} \quad \frac{K^x D^d}{K^b D^d}.$$

Compared to the activity on homozygous *k* cells (type 1), the activity on heterozygous *k/b* (type 2) is reduced as it is on the homozygous recombinant *k/d* (type 3). Moreover F1 mice infected with LCM show stronger immune responses than either parental strain.

It is easy to flaw their proposal either on grounds of plausibility or experimental details. The effects they measure on cytotoxicity are not large and in fact that measured on the heterozygous target and on the homozygous recombinant differ as much from each other as from that on the homozygous parent. In the *in vivo* experiments, the parental strains are not congenic, thus many other factors might be involved in the increased response of the F1. Indeed Koszinowski and Ertl show with vaccinia that F1 mice generate more cytotoxicity when measured on cells of either parent than do the parental strains themselves. In any case, for the argument of Doherty and Zinkernagel, LCM is an unfortunate choice. In this case the augmented immune response in F1 mice leads to quicker death and higher lethality for a given virus dose. This may not be true for all viruses of course (for example Blanden, *Transplantn Rev.*, **19**, 56; 1974) but it does cool the fervour of the embrace of their proposal.

From the point of view of plausibility, theirs seems a weak argument for polymorphism. In the first place, the animal already has several viral proteins to respond to. In addition even with the mechanism of modifying self proteins, there are many other ways to increase the number of surface proteins available for modification without making them polymorphic. Simple repeated duplications would do. It is true these duplications might drift, but there would be no strong demand for new polymorphisms.

Nonetheless, theirs is an attractive idea and an extension of their proposals might bring histocompatibility polymorphism into a central position. Suppose we return to the observations that, for reasons still unknown, T cells respond with high frequency and vigour to other histocompatibility antigens. If we further imagine that interactions with viral protein makes one histocompatibility protein look like some other member of the set, then the apparent preoccupation of T cells with antigens of this set could be put to good use for controlling viral infection. Polymorphism would be advantageous if the special relation to the immune system were maintained for all variants, and if there were repeats in the set of hidden determinants revealed by interaction of the virus with the polymorphic proteins. Otherwise every new histocompatibility antigen variant in interaction with a virus would give determinants outside the set. In sum, this proposal is a specific form of 'molecular mimicry' of histocompatibility antigens by viral proteins (Snell, *Folio biol., Praha*, **14**, 335; 1968).

And if tumour-specific antigens of chemically induced sarcomas were also members of the same set of histocompatibility antigens as recent experiments indicate they might be (Invernizzi and Parmiani, *Nature*, **254**, 713; 1975) then we might be even closer to understanding polymorphic histocompatibility antigens and the apparent preoccupation of the immune system with them.

Morphine and cyclic nucleotides

from L. L. Iversen

UNDERSTANDING the mechanism of action of morphine and other opiates, and the phenomena of tolerance and physical dependence associated with their repeated use, has been for many years one of the major unsolved problems in neuropharmacology. Important progress, however, is now being made in this area. A major breakthrough was the development of biochemical methods for detecting receptors in brain and other tissues, based on the finding that a specific binding of radioactively labelled morphine-like drugs such as etorphine, or morphine antagonists, such as naloxone, could be detected in homogenates of brain (Pert and Snyder, *Science*, **179**, 1011; 1973; Tirenius, *Acta Pharmac. Tox.*, **32**, 317; 1973; Simon *et al., Proc. natn. Acad. Sci. U.S.A.*, **70**, 1947; 1973; see review by Snyder, *Nature*, in the press). Binding experiments of this type have greatly facilitated studies of the precise anatomical distribution of morphine receptors in the brain, and have helped to elucidate the interactions between morphine-like drugs and morphine antagonists and their receptors.

In a search for a simpler model system in which to study opiate effects, a series of tumour cell lines derived from the C1300 neuroblastoma has been screened for the presence of specific opiate binding sites, using labelled naloxone binding. Although specific binding sites could be detected in several cell lines, a hybrid neuroblastoma × glioma line, NG108-15 (also known as 108CC15) was found to have a particularly high density of morphine receptors (Klee and Nirenberg, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 3474; 1974).

This cell line has since been used to test the hypothesis suggested by Collier and Roy (*Nature*, **248**, 24; 1974) that morphine acts as an inhibitor of a prostaglandin-stimulated adenylate cyclase mechanism. Collier and Roy showed that morphine and related opiates blocked the increased formation of cyclic AMP caused by addition of prostaglandin E_1 (PGE$_1$) to homogenates of rat brain. This effect seems to be related to the normal pharmacological actions of morphine because it could be blocked by low concentrations of the specific morphine antagonist naloxone, it was mimicked by the pharmacologically active drug levorphanol but not by its inactive stereoisomer dextrorphan, and the rank order of potencies of several morphine-like drugs in the biochemical test system correlated well with their known analgesic potencies (see Roy and Collier, *Life Sciences*, 1975, in the press). Traber, Fischer, Latzin and Hamprecht (*FEBS Lett.*, **49**, 260; 1974 and *Nature*, **253**, 120; 1975) recently reported that similar phenomena could be observed in the hybrid glioma–neuroblastoma cells which possess morphine receptors. In these cells, as in brain homogenates, morphine and related drugs antagonised the increased formation of cyclic AMP evoked by PGE$_1$ and this effect was stereospecific and blocked by naloxone. Sharma, Nirenberg and Klee (*Proc. natn. Acad. Sci U.S.A.*, **72**, 590, 1975) made similar observations, and found that the drug concentrations needed for

inhibition of adenylate cyclase by opiate drugs, with or without prostaglandin stimulation, correlated well with the potencies of the same drugs in displacing labelled naloxone from receptor binding sites in these cells.

The results obtained in the hybrid cell line, however, cast some doubt on the view that an interaction of opiates with a prostaglandin-stimulated mechanism is a crucial component in their actions Sharma et al., for example, found several cultured cell lines that showed increased formation of cyclic AMP in response to PGE₁, but only in those cells that possessed specific binding sites for opiates was this response blocked by morphine. Even in those cells that did respond to morphine the drug also depressed basal adenylate cyclase activity in the absence of added PGE₁, an effect not seen in brain homogenates. Traber et al. (1974), furthermore, showed that the interaction between morphine and PGE₁ was noncompetitive. All these results suggest that morphine may not act at the same site as PGE₁.

In their most recent paper (this issue of Nature, page 57), Gullis, Traber and Hamprecht describe a novel action of opiate drugs in the hybrid glioma–neuroblastoma cells. They found that low concentrations of morphine and levorphanol (but not dextrorphan) stimulated the formation of cyclic GMP, while depressing the concentration of cyclic AMP. These effects were blocked by naloxone, which by itself at low concentrations had no effect on cyclic nucleotide levels. At higher drug concentrations a somewhat complicated picture emerged, since morphine, levorphanol, dextrorphan and naloxone all caused increases in cyclic AMP levels The latter effects seem unlikely to be associated with the specific pharmacological actions of these drugs. The stimulation of cyclic GMP formation by low concentrations of opiates, however, represents a novel mechanism that could possibly explain the actions of these drugs in reducing cyclic AMP levels and antagonising prostaglandin effects on cyclic AMP, since reciprocal interactions between the two cyclic nucleotides have been found in a variety of other biological situations.

Recent findings by Klee, Sharma and Nirenberg (Life Sciences, 1975, in the press) also provide new insight into the processes of tolerance and dependence at a cellular level. They found that on continued exposure of the cultured hybrid cells to morphine the cells adapted by an increased adenylate cyclase activity. The cells thus show 'tolerance' in the sense that their cyclic AMP contents are similar to those found in normal cells, in spite of the continued presence of morphine, and

Crossed lines

from Pamela Hamlyn

SINCE human beings are inclined to choose their own mates and to produce a mere handful of offspring, it is hardly surprising that mapping of their genes by classical methods has not been as successful as that of the much more accommodating fruit fly. The mapping of human genes, that is, locating them on the twenty-four chromosomes, is of particular interest as an approach to the understanding of human diseases which arise from the inheritance of faulty genes. It is therefore very fortunate that other methods exist for gene mapping. Of these, the formation of a hybrid cell between two different cell types is probably the most important.

Recently a group of scientists working at the National Institutes of Health (Bethesda) have described two different hybrid cell lines which they suggest might be useful for the location of globin genes, and in addition possibly provide information on genetic factors involved in the regulation of their transcription (Deisseroth et al., Proc. natn. Acad. Sci. U.S.A., 72, 1102; 1975).

One of the hybrid cell lines was formed by fusing Friend mouse erythroleukaemia cells with human fibroblasts. The Friend cells grow in culture and synthesise very low levels of haemoglobin but can be stimulated by the addition of dimethylsulphoxide (Me₂SO) so that 20–50% of the cells give a positive reaction for haemoglobin as detected by benzidine staining. The hybrid cells retain most of the chromosomes of both parents but do not synthesise haemoglobin even when Me₂SO is added to the culture medium, although it can be inferred that at least the β-globin gene is retained. This behaviour—the 'extinction' of the characteristic protein of a specialised cell, when that cell is fused with a relatively undifferentiated cell—is a well documented characteristic of this type of cross. In general it is not clear at what site extinction takes place although conjecture favours transcription of the gene. In these experiments a 'probe' of complementary (c) DNA, made by transcribing purified g l o b i n mRNA with reverse transcriptase, has shown that globin mRNA is not present in these hybrids, suggesting

that extinction takes place at the level of transcription or mRNA processing.

The other hybrid cell line described was formed by fusing the same line of mouse erythroleukaemia cells with erythroblasts from human bone marrow. Erythroblasts are red blood cell precursors. They contain globin mRNA as detected by a cDNA probe and haemoglobin as detected by benzidine staining. These Friend cell–erythroblast hybrids behave quite differently from the Friend cell–fibroblast cross. They retain only four human chromosomes but continue to synthesise haemoglobin provided Me₂SO is added to the culture medium. However, although both parent cells are haemoglobin producers, only mouse globin mRNA is detected in the hybrid cells, suggesting that only mouse haemoglobin is being made.

The authors have explained how they think these hybrid cell lines might be used for gene mapping. They propose that in the Friend cell–fibroblast cross the extinction of the mouse globin genes is controlled by a regulatory locus on the human chromosomes. If further chromosome losses were to occur then this locus might be lost, the globin genes re-expressed, and the chromosome(s) involved in controlling globin gene expression defined. Re-expression of originally suppressed genes has been observed in other cell hybrids so that their scheme might be feasible.

The human globin structural genes are probably located on the chromosome normally lost when a Friend cell–erythroblast hybrid is formed since they are not expressed in these hybrids. To assign the genes to chromosomes more accurately, hybrids will have to be isolated which contain only a few more chromosomes than normal Friend cell–erythroblast hybrids but which do synthesise human haemoglobin. If this is accomplished it will be interesting to compare the gene locations with those obtained by hybridising labelled globin mRNA to chromosomes in situ, a method already used to obtain tentative assignments of globin structural genes (Price, Conover, and Hirschhorn, Nature, 237, 340; 1972).

they show 'dependence' in the sense that when the opiate is withdrawn from the cultures cyclic AMP levels rise to abnormally high values. Recovery from the 'addicted' state is slow, as it

requires the return of adenylate cyclase activity to normal values. These results support the suggestions made several years ago that opiates may act as enzyme inducers in the process of

addiction (Goldstein and Goldstein, *Biochem. Pharmac.*, **8**, 48; 1963; Shuster, *Nature,* **189**, 314; 1961). They also agree with the suggestion by Collier, Francis, McDonald-Gibson, Roy and Saaed (*Life Sciences,* in the press) that abnormal formation of neuronal cyclic AMP in brain plays a key part in morphine addiction, and that some of the features of this state can be mimicked by administration of cyclic AMP or phosphodiesterase inhibitors in order to elevate brain cyclic AMP levels.

Another finding that may offer a crucial key to the understanding of the biochemical mechanisms underlying opiate drug actions is the discovery that chemical substances with morphine-like properties occur normally in brain. Hughes (*Brain Res.*, **88**, 295; 1975) recently described the isolation and characterisation of a low molecular weight peptide from bovine brain that is able to mimic the actions of morphine in pharmacological test systems. The new substance, called 'enkephalin', may be a neurotransmitter or modulator substance made and secreted normally in those brain regions that are rich in opiate receptors, and work on its further purification and identification is being actively pursued in several laboratories.

Although research in the area of opiate drugs is progressing at a bewilderingly rapid pace, it is clear that very important new facts are emerging in this hitherto enigmatic field. The combination of opiates, prostaglandins, brain peptides and cyclic nucleotides in a single branch of research is guaranteed to ensure that it will remain a glamour area for some time to come.

New support for autoimmune basis of myasthenia gravis

from Angela Vincent

The fifth conference on myasthenia gravis was held in New York on May 30–31.

MYASTHENIA GRAVIS (MG) is a disorder of neuromuscular transmission which is relatively rare but can be extremely disabling. It is characterised by weakness and increased fatiguability of skeletal muscle which can be improved by acetylcholinesterase inhibition. Myasthenia is associated with thymic hyperplasia (75%) and thymoma (15%). Antibodies to skeletal muscle and thymic myoid cells have been demonstrated in about 30% of patients, and thymectomy often induces a remission. These features of the disease and its association with other immune disorders led Simpson

(*Scot. Med. J.,* **5**, 419; 1960) to propose that an autoimmune mechanism might be responsible, but attempts to implicate a serum factor blocking transmission have been largely unsuccessful.

Electrophysiological studies on biopsied intercostal muscle from MG patients by Elmqvist *et al.* (*J. Physiol., Lond.,* **174**, 417; 1964) showed reduced amplitude of miniature endplate potentials (m.e.p.ps) and it was suggested that there might be a reduction in the size of individual acetylcholine quanta released from the presynaptic nerve terminal. The possibility remained, however, that there might be reduced sensitivity of the postsynaptic membrane to released acetylcholine. This seems possible, since the total number of acetylcholine receptors has now been shown to be reduced in endplates from MG patients (Fambrough *et al., Science,* **182**, 293; 1973; Green *et al., Phil. Trans. R. Soc.,* **B270**, 551; 1975). However, there are morphological changes in MG endplates (Engel and Santa, *Ann. New York Acad. Sci.,* **183**, 46; 1971) and there is, as yet, no evidence as to whether this reduction in total numbers of receptors represents a reduction in density of functional receptors per unit area.

The first day of the meeting was concerned with neuromuscular transmission in MG and in a new animal model. In the last few years, many groups have purified the acetylcholine receptor (AChR) from the electroplax of electric eel and *Torpedo*. α-Bungarotoxin (α-Bgt), a snake toxin which blocks neuromuscular transmission irreversibly, has been used to assay the AChR in solution and in skeletal muscle. Antibodies raised in rabbits against electric eel AChR cross react with the animals' own AChRs *in situ* and produce progressive weakness, similar in many respects to that found in MG (Patrick and Lindstrom, *Science* **180**, 871; 1973). Several speakers presented results from rabbits immunised against AChR from eel and *Torpedo*. A few days after the second injection, the animals developed weakness, usually progressing to death. Anticholinesterase treatment temporarily improved their condition. A decremental response to repetitive nerve stimulation could be demonstrated and m.e.p.p. amplitude was reduced. Circulating antibodies against electroplax AChR could be shown by *in vitro* techniques and by their ability to block carbachol-induced depolarisation in the intact electroplax.

J. M. Lindstrom (Salk Institute, La Jolla) described immunisation of rats with a single intradermal dose of eel AChR in adjuvants. About 8 days later they developed an acute episode of paralysis from which most recovered

in a few days. This was associated with severe focal degeneration of the muscle endplate and inflammatory infiltration of the muscles (A. G. Engel, Mayo Clinic, Rochester). V. A. Lennon (Salk Institute) showed that this was probably due to cell-mediated hypersensitivity: it could be abolished by prior thymectomy and could be transferred by T (thymus-derived) lymphocytes into X-irradiated recipients. A second chronic stage was also encountered in these animals. It began at about 30 days and was preceded by a rise in serum antibodies against the AChR. Morphologically the endplates had undergone repair, but the new junctions were simpler than normal and resembled those found in MG. There was evidence of neuromuscular block, reversed by anti-cholinesterase, but these animals did not show such severe weakness as the rabbits. The m.e.p.p. amplitude was reduced, however (E. M. Lambert, Mayo Medical School, Rochester), and the difference in clinical findings between rats and rabbits was thought to be due to the larger number of acetylcholine quanta released per impulse from rat terminals.

Is there a circulating antibody to the AChR in myasthenia gravis?

A. Bender (National Institute of Neurological Disease, Bethesda) showed that sera from patients with MG could inhibit an indirect labelling technique for AChR in cross sections of normal human muscle. S Appel (Duke University Medical Center, Durham, North Carolina) and J. Lindstrom were able to detect binding of immunoglobulins from MG sera to Triton-solubilised receptors from normal human muscle;

but this binding did not appear to involve the acetylcholine recognition site of the receptor. Nevertheless, D. B. Drachman (Johns Hopkins University, Baltimore) had induced electrophysiological evidence of MG in immunosuppressed mice by repeated injections of MG globulins over a period of 10 days.

On the other hand, J Keesey (University of California, Los Angeles) was unable to demonstrate any inhibitory effect of MG serum on α-Bgt binding to mouse diaphragm; E. X. Albuquerque (University of Maryland, Baltimore) had found no reduction in acetylcholine sensitivity in rat or human endplates after treatment with serum from MG patients; and injection of serum globulins or lymphocytes into rats produced no electromyographical evidence of neuromuscular block (T. Namba, Maimonides Medical Center, Brooklyn). Were these negative results due to immunoglobulins being unable to penetrate the intact neuromuscular junction? B. Fulpius (University of Geneva), using α-Bgt-labelled muscles and radioactively-labelled anti-α-Bgt in vivo and in vitro, clearly showed that the antibody was able to penetrate and bind to the motor endplate.

The second day was concerned with genetic, immunological and clinical aspects of MG. Histocompatibility antigens HL-A₂ and HL-A₈ were shown to be more prevalent in MG patients than in the normal population and divided the patients into two main groups: HL-A₂ being more common in older patients with thymomas and circulating antibodies to skeletal muscle, and HL-A₈ being associated with young females with thymic hyperplasia and no circulating antibodies (M. J. Oosterhuis, Wilhelmina Gasthuis, Amsterdam). The relative proportion and absolute numbers of T and B lymphocytes in MG were reported by several speakers, but no consistent pattern emerged from most of these studies G. Birnbaum, however (Cornell University Medical College, New York), found decreased T-cell function in young, hyperplastic patients, and a significant rise in T cells and T-cell function after thymectomy Further immunological studies may well be easier to relate to the disease process if tissue typing is included.

The effect of immunosuppressant therapy was discussed and various regimens for steroid treatment suggested. One interesting aspect presented by G. Matell (Karolinska Institute, Stockholm) was drainage of the thoracic duct undertaken in severe cases These patients improved remarkably after 24–48 hours of drainage, although their condition deteriorated within 1–2 weeks of stopping the treat-

ment. In contrast, injection of the cell-free lymph back into the same patients produced deterioration within 30–60 minutes.

The animal models presented at this meeting showed considerable similarity to MG. Circulating antibodies raised against solubilised AChR can bind to, and directly block the receptor in situ; cell-mediated hypersensitivity to the receptor can produce symptoms of an acute nature, and it may be a necessary prelude to the humoral response in rats. Whether there is a circulating antibody in MG directed against the acetylcholine recognition site of the AChR, and capable of directly blocking the receptor, is still doubtful. It is possible, however, that the immunoglobulins that bind to solubilised human receptors, as shown independently by Appel and Lindstrom, have an indirect inhibitory effect on neuromuscular transmission in situ.

Denervation and re-innervation

from Shin-Ho Chung

BEFORE a foetal muscle is innervated, the fibre is 'supersensitive' to the chemical transmitter acetylcholine over its entire length. When a motor nerve forms an excitable junction with the muscle fibre, the chemosensitive area shrinks progressively and becomes restricted to the junction and its immediate surroundings (Diamond and Miledi, J. Physiol., Lond., 162, 393; 1962). A similar process occurs in adult muscle fibres following regeneration after destruction of the nerve (Miledi, J. Physiol, Lond., 151, 1, 1960; Axelsson and Thesleff, J. Physiol., Lond., 147, 178, 1959). Interest in this system stems partly from the fact that, during their supersensitive period, muscle fibres accept innervation from foreign

Pollution from plants

from Peter D. Moore

IT is both well known and a source of considerable concern that the particulate matter of the atmosphere contains a burden of toxic heavy metals (see Nature, 247, 510; 1974). In south-west England attempts have been made to monitor the fallout of heavy metals by analysing their levels in superficial leaf washings and in cuticular layers on vegetation (see, for example, Little, Environ. Pollut., 5, 173; 1973) The reverse situation is described by Beauford, Barber and Barringer in this issue of Nature (page 35); they have shown that heavy metals from the soil are absorbed by plant roots, are translocated and eventually released into the atmosphere in particulate form, perhaps with fragments of cuticular waxes. It has been realised for several years that plants can generate atmospheric particulate matter, but this is the first clear demonstration, using radioactive tracer techniques, that the movement of heavy metals from soil to atmosphere may accompany this process

This being so, it may be necessary to reconsider the use of vegetation as a convenient filter by which heavy metal fallout from the atmosphere can be monitored. It is not usually known what proportion of cuticular and epicuticular metal is derived from the soil through the plant In many situations the soil levels of heavy metals also reflect atmospheric fallout, in which case the leaf washings will still provide a useful index, but this is not so

where metals in soils are derived from other sources.

But perhaps the most important implication of this work, as the authors point out, is that industrial activity is not the sole source of atmospheric heavy metals. The question which must now be asked concerns the respective importance of these two sources. Here an answer may be found in palaeoecological work by Lee and Tallis (Nature, 245, 216; 1973), who analysed the lead contents of peat samples taken from depths down to 2 m at an upland site in Derbyshire. Lead contents of almost 600 p.p.m. were found in the upper 20 cm of peat, but these fall to about 40 p.p.m. at depths below 20 cm (dated by radiocarbon determination at pre 1460 AD). At depths below 125 cm, the leaf level falls yet further to a fairly steady value of about 10 p.p.m These samples predate the Roman conquest, during which there was some lead mining and smelting, hence it must reflect the background level of atmospheric lead, to which the vegetation is presumably making its contribution. Thus, even if this background were entirely due to the production of metal-containing particulate matter from plants, the current industrial and domestic production of lead still exceeds it by sixty times. In the midlands of England, therefore, atmospheric lead production by vegetation must be regarded a very minor contribution to the atmospheric content of heavy metals when compared with human sources.

nerves, with which they normally do not connect (Fex *et al., J. Physiol., Lond.,* **184**, 872; 1966). These phenomena pose several salient questions. For example, what causes the spread of chemoreceptors after denervation? Is the development of high sensitivity to a transmitter substance a prerequisite for the establishment of a synaptic connection? What happens to 'incorrect' junctions when 'correct' nerves re-innervate muscle fibres? An article by Frank, Jansen, Lømo and Westgaard (*J Physiol., Lond.,* **247**, 725–748; 1975) highlights these questions.

It was originally believed that a 'neural factor' released from nerve terminals prevented the spread of receptors beyond the synaptic region. Subsequent experiments showed this to be implausible. When nerve impulses flowing towards the muscle are blocked with an anaesthetic, while leaving the nerve otherwise undamaged, the muscle membrane becomes supersensitive, as it would if the nerve were cut. The development of supersensitivity can be prevented either by chronic nerve stimulation distal to the region of the block, or direct stimulation of the denervated muscle (Lømo and Rosenthal, *J. Physiol., Lond.,* **221**, 493, 1972; Frank *et al.*). These studies show that contractile activity of muscle fibres, innervated or denervated, inhibits the formation of extra-junctional receptors.

Because connections are formed only when muscle fibres are supersensitive to acetylcholine, it is tempting to postulate that the receptors are the membrane component w h i c h directly controls synapse formation. A pointer in this direction is the fact that the formation of contacts between denervated muscle fibres and foreign nerves can be arrested by maintaining the muscle activity by direct stimulation (Jansen *et al., Science,* **181**, 559, 1973; Frank *et al*). However, a recent demonstration (Van Essen and Jansen, *Acta physiol. scand.,* **91**, 557, 1974) that re-innervation proceeds normally in the presence of α-bungarotoxin, which binds irreversibly to acetylcholine receptors, makes such a generalisation premature.

There is conflicting evidence on the fate of 'incorrect' junctions when 'correct' junctions are re-formed. An earlier preliminary report (Cass *et al., Nature,* **243**, 201, 1973; *Nature,* **243**, 185; 1973) claimed that 'correct' fibres render ineffective 'incorrect' synapses in axolotl muscles, while leaving them structurally intact. Such a suppression of 'incorrect' junctions is known to occur in mammalian skeletal muscles during development (Redfern, *J. Physiol., Lond.,* **209**, 701; 1970; Bagust *et al., J. Physiol., Lond.,* **229**, 241; 1973). Frank *et al.* now show that both

foreign and original synapses can co-exist functionally for prolonged periods of time in adult mammalian muscles. Thus the ability to suppress inappropriate synapses is apparently lost in mature skeletal muscle.

The underlying cellular mechanism for afferent–efferent interaction, as illustrated by the denervated neuromuscular system, remains one of the mysteries in neurobiology. During the process of synaptogenesis in the nervous system, a target cell becomes receptive, selects an appropriate input, and suppresses the inappropriate ones. It is only through a combined immunological, biochemical and neurophysiological study of a simple system, such as the innervation of developing or denervated muscle, that we will gain insight into the rules governing the formation of specific nerve connections.

Hole transport in silica

from Andrew Holmes-Siedle

SILICA (SiO₂) is a very important material in solid state physics, electronics and optics. Although the crystal structure of quartz is complex and several inconvenient phase transitions of the lattice occur, the material is, on the whole, very well characterised. The amorphous form, fused silicon, presents a useful example of the simplest form of disorder, the only deviation from order being some variation in the Si–O–Si bond angles. In optics, the near-zero expansion and high ultraviolet transmission are extremely useful and, in electronics, the crystalline form is used in piezoelectric devices and the amorphous thin-film form is an essential part of all current forms of metal-oxide-semiconductor (MOS) device. Of course, the fact that quartz and silicates are the commonest minerals also help to make silica a technologically and economically important material.

The band-gap of SiO₂ is of the order of 9 eV and thus the electronic transport properties are not easily studied. But, as I discussed previously (*Nature,* **246**, 190; 1973), studies of the motion of electrons and holes in this material are now coming on apace. One of the motives for this work is the need to understand carrier transport in MOS systems and another is the general need to operate insulators under extremes of electric field or photon excitation. In the earlier article, the work of Hughes on electron transport in quartz and fused silica slabs—measuring photoconductivity after nanosecond pulses of X rays—was described. At that time, Hughes's results confirmed the general feeling that all cur-

rent was carried by electrons and that holes were virtually immobile, possibly being lattice-trapped in non-bonding oxygen orbitals (see, for example, Di Stefano and Eastman, *Phys. Rev. Lett.,* **27**, 1560; 1971). Some further measurements by Hughes (*Appl. Phys Lett*, **26**, 436; 1975) have now demonstrated a small contribution of the holes to photocurrents. The fact of the smallness is of great interest and will help towards clearing up controversy in the important field of carrier trapping in some insulators.

Hughes's measurements are summarised in the figure, which shows that, whereas electrons travel rather easily through the SiO₂ lattice, suffering only longitudinal optical phonon scattering, holes can essentially be 'frozen' at low temperature but still possess a measurable mobility at room temperature. This explains a hitherto puzzling result of Powell and Derbenwick (*IEEE Trans. nucl. Sci.,* **NS18**, no. 6, 99, 1971) who irradiated a 200 mm SiO₂ film with 10.2 eV light. Although the light was largely absorbed within a few nanometres of the surface, a positive charge sheet was found at the unilluminated side of the film, suggesting a finite mobility of holes or ions at room temperature. Arguments that ions were carrying charge are now unnecessary and, in general, the important work of distinguishing ionic from electron–hole transport effects in thin films, especially in MOS devices, can perhaps now proceed in a more orderly fashion.

The use of pulsed X-ray-induced photoconduction may become a useful general solid-state tool and will clearly
Mobility of holes and electrons in amorphous silicon dioxide films against reciprocal temperature, demonstrating differences in transport mechanism.

play a part in the important general question of charge motion and storage in wide-band solids.

Planetary collisions

from David W. Hughes

AT the dawn of the Solar System collisions between planets could have been so frequent and devastating that we now see only the scattered remnants of this scrummage. Interaction between planets in their present orbits is minimal, a situation which slowly built up as the Solar System aged. But small bodies, such as comets and asteroids, often have orbits which cross those of the planets and thus are intrinsically unstable. They may be eliminated by collision with a planet—either accreting to the planetary surface or (more rarely) being fragmented when they graze the planet's upper atmosphere—or they may be perturbed—either into shorter period orbits with aphelia near the planet's orbit (like the Jovian family of comets) or into hyperbolic orbits which take them out of the Solar System (like the space probes Pioneer 10 and 11).

Probabilities of encounter were first calculated in a classic series of papers by Öpik. Two fundamental approaches can be made to the problem, the analytical one which considers individual particles and their orbital elements and the numerical integration approach which uses random walk and Monte Carlo techniques applied to a large number of particles. These two approaches have been combined by Weidenschilling in a recent paper in *The Astronomical Journal* (**80**, 145; 1975). The probability of encounter between two objects with intersecting orbits is found to be simply a function of their relative velocities and one angular variable. These encounters will eventually occur even between particles with crossing orbits (orbits with the same range of heliocentric distances) because secular perturbations cause nodal precession and advancement of the perihelion, which finally results in intersections and then encounters.

Öpik (*Adv. Astron. Astrophys.*, **2**, 219; 1963) found that the mean lifetime of the Apollo group of asteroids (which have orbits crossing those of Earth and Mars) is 10^8 years. Collisions would have caused their numbers to decay exponentially with time. So if these asteroids are remnants of an original group formed 4,500 Myr ago at the birth of the Solar System, there would have been 2.5×10^{19} of them at $t=0$, equivalent to a mass one hundred times that of the Sun. Clearly this is most unlikely, and thus the asteroids in this group cannot be permanent

members of the Solar System but must be continually replenished from the asteroidal belts and comets.

Weidenschilling comments on the differences in the encounter probability curves of the terrestrial and Jovian planets. This is partly explained by the great mass of Jupiter making it more likely than the inner planets to encounter material. But the mass of the planet also affects the ultimate fate of the small bodies encountered. The terrestrial planets, with orbital velocities several times greater than their escape velocities, have effective cross sections such that the ejection probability is only an order of magnitude higher than the collision probability. For Jupiter the orbital velocity is less than the escape velocity, the collision cross section varies with Joviocentric velocity and about 1,000 more particles will be ejected from the Solar System by Jupiter than collide with it.

Weidenschilling's figure for the probability of ejection by Jupiter is an order of magnitude greater than Öpik's whereas his results for the terrestrial planets agree with those of Öpik. If Weidenschilling's Jupiter result is correct, the time scale for the dynamical elimination of comets must be two to four orders of magnitude greater than the time scale for disintegration. Thus the fact that thousands of dead cometary nuclei are not observed indicates that most comets disintegrate completely or that the dead nuclei are too small to be seen.

The equations given in Weidenschilling's paper also enable the efficiency of cometary ejection processes to be calculated. The author promises to apply these to the production of the Öort cloud of distant comets in a later paper. He also speculates that the total mass and angular momentum lost from the Solar System by cometary ejection might be of cosmogonical significance, indicating that the Solar System's angular momentum–mass balance might have varied with time. □

Type B hepatitis a kissing disease?

from Arie J. Zuckerman

THOUGH the importance of the parenteral and inapparent parenteral route of transmission of hepatitis B infection has long been recognised, it has become difficult to incriminate parenteral transmission in all cases of infection with hepatitis B virus (*Tech. Rep. Ser.* No. 570; World Health Organisation, 1975). Interest in various mechanisms of spread of this infection has flourished in recent years following the experimental demonstration of infectivity of serum by the oral route and epidemiological studies implying the possibility of venereal transmission of hepatitis B (*Nature*, **246**, 59; 1973). Although the reported detection of hepatitis B surface antigen in semen and menstrual blood obtained from individuals with antigenaemia offers possible explanations for infection by the sexual route, the matter is far from settled.

The presence of hepatitis B surface antigen in a variety of body fluids and excretions such as urine, colostrum, milk, saliva, bile, faeces and sweat has not been consistently confirmed. In particular confirmation of the finding of the antigen in bile and faeces is still lacking in spite of intensive studies in various laboratories.

A recent report from Costa Rica has shed some light on possible non-parenteral routes of transmission of hepatitis B in endemic settings (Villarejos *et al.*, *New Engl. J. Med.*,

291, 1375; 1974). Serial samples of faeces, urine and saliva collected from chronic carriers of hepatitis B surface antigen and from patients with acute hepatitis B were tested by radioimmunoassay. The antigen was not found in any of 120 faecal extracts examined. The antigen was detected in three of 130 urine samples and all the positive samples contained occult blood. 274 saliva specimens from 93 chronic carriers were tested and the antigen was found in nearly 60% of specimens belonging to 75 subjects. It is interesting to note that the antigen was not found constantly in the saliva of the carriers, although all had circulating antigen at the time of sampling. Antigen was found in the saliva of 76% of 41 patients with acute hepatitis B, mainly during the first three weeks after the onset of clinical symptoms. The presence of the surface antigen in saliva both in carriers and in patients with the acute disease was not related to contamination with blood. These results show that salivary transmission may be a major mechanism of spread of infection in an area where hepatitis B occurs endemically. Villarejos and colleagues conclude therefore that transmission may occur directly by mouth-to-mouth kissing and in children by exchange of chewed toys and sweets. This presupposes of course that the antigen found in saliva is actually infective.

Prostaglandins and their intermediates

from a Correspondent

> An international conference on prostaglandins was held in Florence on May 26–30.

ARGUABLY the most exciting findings of the whole meeting were revealed by S. Samuelsson (Karolinska Institute, Stockholm) in an introductory address. Recently Samuelsson's group found (Hamberg and Samuelsson, *Biochem. Biophys. Res. Commun.*, **61**, 942; 1974 and *Proc. natn. Acad. Sci. U.S.A.*, **71**, 3400; 1974) that PGG₂ and PGH₂, the endoperoxide precursors of prostaglandins (see *Nature*, **253**, 88; 1975), can, in lungs and platelets, also be transformed into other (non-prostaglandin) products including a hemiacetal derivative 'PHD'. Now Samuelsson's group have identified a very labile intermediate in the conversion of PGG₂ to PHD. This new intermediate does not have a classical prostaglandin structure and has been named 'Thromboxane' (see figure), because it is a very potent platelet aggregating agent. Since it is the first member of a new series of compounds and contains two double bonds it was further designated 'Thromboxane A₂': its metabolite PHD now becomes 'Thromboxane B₂'.

Thromboxane A₂ has at least two other interesting properties; its half-life in aqueous solutions is about 30 s, and it strongly contracts strips of rabbit aorta. As a product of the prostaglandin biosynthesis cascade its generation is of course blocked by aspirin. These properties make it very likely that Thromboxane A₂ is in fact 'RCS'—the mysterious rabbit aorta contracting substance (released from lungs during anaphylaxis), first described by Piper and Vane in 1969 (*Nature*, **233**, 29). The importance of the endoperoxide system in platelet aggregation was emphasised by the Karolinska group's discovery of a subject deficient in the cyclo-oxygenase system (which converts arachidonic acid to PGG₂). Platelets from this subject showed reduced sensitivity to the aggregating action of adrenaline and collagen, but were aggregated by PGG₂. The idea that the endoperoxides themselves, or their non-prostaglandin end products, may be important in other systems was later reinforced by M. Hamberg *et al.* (Karolinska Institute) who found elevated levels of endoperoxide and Thromboxane metabolites in perfused guinea-pig lung during anaphylaxis; PGG₂ and H₂ also had much more marked bronchoconstrictor activity than PGF₂α. Both pieces of evidence suggested that the endoperoxides (or

their non-prostaglandin metabolites) could be important in the anaphylactic reaction. J. Vane (Wellcome Laboratories) presented evidence that PGG₂ and PGH₂ potentiated the inflammation produced in the rat paw by stimuli such as Carraggeenin.

The question of the cellular origin of the substrate required for prostaglandin biosynthesis received some attention, though not perhaps as much as it deserved. Phosphatidylinositol was definitely implicated as a source of arachidonate for, prostaglandin biosynthesis in the pig thyroid undergoing TSH stimulation (B. Haye, S. Champion and C. Jaquemin; Reims-Cédex, France) and in platelets exposed to a variety of aggregating agents (Iacona and Schoene, US Dept. of Agriculture, Beltsville). Some data from Vane's group suggested that phosphatidylcholine was the source of the arachidonic acid liberated during trauma of spleen tissue, and demonstrated that inhibition of phospholipase A₂ could prevent this initial step in the generation of prostaglandins from occurring.

The section dealing with metabolism of prostaglandins aroused less interest: prostaglandin 15-hydroxy-dehydrogenase (PGDH) has been successfully extracted and purified from a variety of sources allowing good kinetic data to be obtained. One particularly ingenious and successful method of purifying the enzyme—by affinity chromatography using prostaglandins

Alternative pathways of arachidonic acid metabolism in platelets. I, Conversion by a lipoxygenase of arachidonic acid to an ω-9 hydroperoxide which is subsequently reduced to the corresponding hydroxy acid. II, Conversion of arachidonic acid by a cyclo-oxygenase to PGG₂. III, Conversion of PGG₂ to a 17C-(ω-6) hydroxy acid and malondialdehyde. IV, Conversion of PGG₂ to PG E₂/F₂ ₐ. This pathway is of minor importance in platelets. V, Conversion of PGG₂ to Thromboxane A₂ and Thromboxane B₂ (PHD). PHD is a hemiacetal derivative of 8(1-hydroxy-3-oxopropyl)-9, 12L-dihydroxy-5, 10-heptadecadienoic acid.

as the ligand—was presented by E. Oliw, I. Lunden and E. Änggard (Karolinska Institute). Throughout the conference, however, many workers were disappointed that so little attention was paid to the question of inhibiting this important enzyme: a really effective inhibitory drug would complement the use of the aspirin-like agents (inhibitors of prostaglandin biosynthesis) as a pharmacological tool to investigate the function of prostaglandins in the body. R. Flower *et al.* (Wellcome Laboratories) presented evidence that PGDH was a short-lived enzyme within the cell, the tissue levels falling very quickly after the administration of protein synthesis inhibitors.

Details of two important radioimmunoassay systems were presented at the meeting: F. Dray, B. Charbonnel and J. Maclouf (Pasteur Institute, Paris) have devised techniques which eliminate most of the artefacts associated with the measurement of E and F-type prostaglandins in plasma and have thus reduced the falsely high readings obtained by many early workers. Their plasma levels for E-type prostaglandins of <5 pg ml⁻¹ and for the F-type of $\leqslant 12$ pg ml⁻¹ are probably the lowest recorded. Because prostaglandins are metabolised so rapidly, it is often more desirable to measure the major plasma (13, 14 dihydro-15 keto) or urinary (tetranor dioic acid) metabolites of prostaglandins. E. Granström (Karolinska Institute) presented some beautiful data on immunoassay systems designed for these purposes. The levels of metabolite were found to fluctuate throughout the oestrous cycle and were depressed during treatment with aspirin-like drugs. Confidence in the validity of both these assay systems was increased by the demonstration that the blood levels found corresponded well with those predicted from daily prostaglandin production rates.

Two clinical syndromes associated with the prostaglandin system were described: the platelet cyclo-oxygenase deficiency reported by Samuelsson's group (see above), and 'hyperprostaglandinaemia'—a syndrome probably due to a deficiency of PGDH—reported by A. Labrum, M. Lipkin and F. Dray (University of Rochester, New York and the Pasteur Institute, Paris). This condition was associated with periodic headache, vomiting, abdominal pain, diarrhoea and pyrexia.

Because of the arrangement of the conference, it was not possible to attend every session, so only certain aspects of the meeting are reported here. But it was clear that the impression felt by many at the end of this exciting conference was that the physiological role of prostaglandins—and now of their intermediates too—was as elusive as ever.

Buried Mesozoic volcanic–plutonic fronts of the north-western Pacific island arcs and their tectonic implications

Jiro Segawa
Ocean Research Institute, University of Tokyo, Tokyo, Japan

Shoichi Oshima
Hydrographic Office, Maritime Safety Agency, Tokyo, Japan

Detailed magnetic surveys around the islands of Japan have revealed the presence of Mesozoic volcanic and plutonic belts at depth beneath the continental shelf. These belts, which can be correlated with those on the mainland of eastern Asia, provide a record of the migration of island arcs since the opening of marginal seas during the Tertiary.

DETAILED surveys (refs 1, 2 and Geographical Survey Institute, Japan, unpublished) have revealed remarkable features in the total magnetic intensity anomalies around Japan and the surrounding continental shelf and magnetic anomalies from Russian data[3,4], and oceanic magnetic lineations compiled by Uyeda *et al.*[5] have also provided evidence of some interesting features (Fig. 1).

Most significant is the discovery of a north–south, positive anomaly belt coupled with a narrower negative belt to the west, running from the eastern side of north-eastern Honshu to the southern part of Hokkaido (Fig. 1 i) with a maximum amplitude exceeding 500 nT. A similar positive anomaly belt runs from the south-east of Hokkaido to Kamchatka, along the Kuril Island Arc (Fig. 1 ii). These two magnetic lineations can be distinguished from lineations in the oceanic basins because their locations coincide with the continental crust. Furthermore, the trend intersects that of the oceanic lineations (Fig. 1 iv) in the western Pacific Basin up to the Japan Trench. Oceanic anomaly iv (Fig. 1) disappears in the middle of the continental shelf in the Japan Trench approximately at the location of the 3,000-m isobath. As the crust under the landward slope of the Japan Trench is not oceanic, the presence there of oceanic anomalies suggests that oceanic crust has been thrust beneath the island arc. By the same reasoning we believe that the positive magnetic lineation (Fig. 1 iii) which is observed at the landward slope of the Kuril Trench and which is roughly parallel to both the trench and the oceanic lineations, is of oceanic origin. Other positive magnetic lineations at ocean-to-continent boundaries occur at Primorye, Sikhote-Alin, Sakhalin and in the Okhotsk Sea (Fig. 1).

The correlations between the positions of the isolated, patch-shaped, positive (or negative) magnetic anomalies in the middle of Honshu and Hokkaido and the line of Quaternary volcanoes known as the Quaternary Volcanic Front (QVF)[6] (Fig. 1) are remarkable. Approximately 30 km east of the QVF (Fig. 1) a Miocene volcanic front has been identified geologically but is not clearly reflected by the magnetic anomalies.

Identification of buried Mesozoic volcanic–plutonic belts

Figure 2 shows profiles of total magnetic intensity anomalies, and bathymetry and magnetisation models which can account for the magnetic anomalies that cross the two continental magnetic lineations (Fig. 1i and ii). The magnetic anomalies along line *A* in Fig. 1 can be modelled by a two-dimensional magnetised block trending north–south, with an intensity of magnetisation 5×10^{-3} e.m.u. cm^{-3}, a direction of magnetisation of N45°W and an inclination of 53°. The magnetised block is 20 km thick with its top 10 km below the ocean. The most important characteristic of this model is that its magnetisation is largely westerly, in contrast to the present magnetic field, which suggests lineation i (Fig. 1) is caused by a westerly remanent magnetisation. Even if the magnetic anomalies are affected by magnetisation induced by the present magnetic field, the westerly tendency of the remanent magnetisation is by no means altered; on the contrary, it would be further emphasised. The magnetic anomalies along line *B* (Fig. 1), on the other hand, can be explained by a two-dimensional block trending ENE to WSW, magnetised with an intensity of 5×10^{-3} e.m.u cm^{-3} in the direction of the present field. Almost the same results can be expected from the other sections of the continental magnetic lineations i and ii.

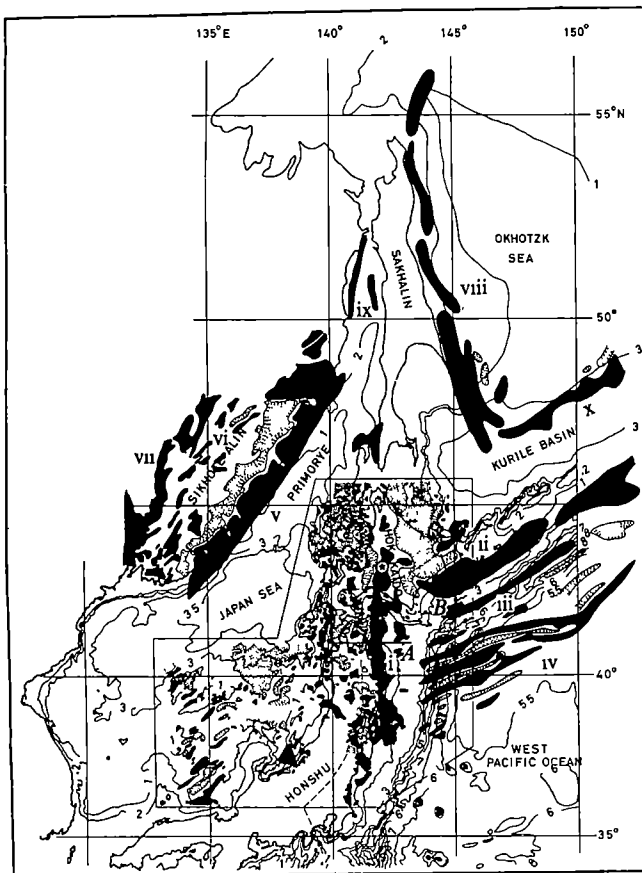
The fact that lineation i may result from a westerly remanent magnetisation is consistent with the natural remanent magnetisation of the Lower Cretaceous granitic samples obtained by Kawai *et al.*[7] from the Kitakami and the Abukuma massifs in north-eastern Honshu. They proposed an anticlockwise rotation of north-eastern Honshu and a clockwise rotation of south-western Honshu some time after the Lower Cretaceous. As the continental magnetic lineations exist in areas of continental crust, and as a rotation of Japan should accompany any rotation of continental crust, the estimated westerly remanent magnetisation could be further evidence of the anticlockwise rotation of north-eastern Honshu. The magnetisation of lineation ii, on the other hand, cannot necessarily be taken to indicate the absence of rotation with respect to the Hokkaido–Kuril–Kamchatka Arc, because of the nearly east–west geographical trend of the supposed magnetised block. Although it is uncertain whether or not the magnetisation of lineation ii deviated in direction from the present magnetic field, we assume that lineation ii results mainly from a remanent magnetisation with approximately the same direction as the present magnetic field, and that little or


Fig. 1 Total magnetic intensity anomalies in and near Japan. The area enclosed by solid lines has been measured in detail in runs approximately 2 miles apart. Bathymetric contours are in metric units. Asterisk, site of a test drilling in the Sorachi region, Hokkaido.

no appreciable rotation has occurred with respect to the Hokkaido–Kuril Arc.

There are two lines of evidence from which the material which causes the continental magnetic lineations can be identified: a test drilling[8] at Sorachi Province, Hokkaido, which coincides with the northern end of lineation i; and the result of measurements[9] of magnetic susceptibilities and remanences of the drilling cores (Fig. 3). The drilling went down to a depth of 3,712.97 m, where the drilling bits hit a basement layer. The basal layer dips from west to east, and the

sedimentary layers show significant unconformities (Fig. 3). Analyses of gravity anomalies combined with geology and drilling results[10] indicate that the basal layer consists of metamorphosed basic volcanics of Lower Cretaceous age, corresponding to the eastern slope of an anticline which aligns with lineation i. The magnetic susceptibilities of the drilling cores (Fig. 3) indicate that the metamorphosed basic volcanics of the basal layer are as strongly magnetised as the recent volcanics. These measurements have also shown that the magnetic Q ratio of the basement rocks is 1 or somewhat smaller. Although it is not certain whether the anticlinal basement is the origin of lineation i, we think it probable that either the anticlinal basement or a belt of ultramafic dyke material beneath it may be responsible for the anomaly. If that is so it can be inferred that volcanic–plutonic activity was initiated in Lower Cretaceous times or earlier, below the lineation. This volcanic–plutonic belt may be compared to the belts of Mesozoic volcanic–plutonic outcrops[11] on the Japan Sea side of south-western Honshu. As for lineation ii, no drilling data are available at present. But the areas are known to be abundant in Cretaceous volcanics, serpentines and other rock types[12], which seems to indicate the existence of Cretaceous igneous activity.

Comparison with other continental magnetic lineations

Magnetic anomalies in the Primorye and Sikhote-Alin provinces of eastern Asia show a distinct correlation to the belts of intrusions of intermediate to ultrabasic compositions[13]. The two eastern lineations (Fig. 1 v and vi) are located at both sides of the Sikhote-Alin granitic massif. One of the lineations, which runs along the coast of eastern Primorye and extends over the continental shelf on the Japan Sea side, is a coupled belt comprising a negative belt on the west and a positive belt on the east. Although the amplitudes of the magnetic anomalies are not reported in the Russian data, we judge, from the trend of the lineation (about N40°E), that along the coast of eastern Primorye lineation v is caused by a normally magnetised block, though the absence of negative anomaly belts associated with lineations vi and vii, which have the same trend, is not easily explicable. The close correlation between the ultramafic intrusive belts of eastern Asia and the magnetic lineations could indicate that the magnetic anomalies east of north-eastern Honshu are also caused by ultramafic intrusions. The orogenesis of the Sikhote-Alin Massif is supposed to have occurred during the Upper Cretaceous. Although the ages of the intrusive rocks around its sides are not reported, we think it likely that the Sikhote-Alin orogenesis is intimately related to the neighbouring intrusions (which therefore also occurred in the Upper Cretaceous or later). The sources of the magnetic lineations at Sakhalin and along the northern margin of the Kuril Basin are not known. We

W   E

which it takes for a buried dyke to cool from 1,000 °C down to 500 °C indicates that about 10 Myr are needed[15]. Such a long cooling time together with the slower accumulation of intrusive materials suggests that at least several million years of steady magnetic polarity would be necessary before a continental intrusion can become magnetised in a fixed direction. Therefore, only two possible ages—Jurassic and Cretaceous—can be assigned to the intrusive belts. Thus, we think that most of the magnetisation which produced lineations i and ii may have been acquired during the long Cretaceous normal epoch, presumably between the Aptian and the Albian. On the other hand, the intrusions found at Primorye, which look somewhat younger than those of Honshu, may have been magnetised during the Cenomanian–Turonian. It is interesting that if this hypothesis is correct, the smooth magnetic zones of the oceanic basins correspond to the most magnetically anomalous areas of the continents.

assume, however, that they are all caused by basic or ultramafic intrusions.

Dating of the continental magnetic lineations can be attempted using the magnetic reversal time scale. The Mesozoic magnetic reversals[14] include two epochs during which the magnetic polarity remained normal for a long time: the first occurred before the Kimmeridgian (148 Myr BP); the second during the Aptian–Comacian (111.5–84.5 Myr BP). As remanent magnetisation is produced only when magma has cooled sufficiently, a steady remanent magnetisation cannot be acquired by continental intrusives (which seem to accumulate much more slowly than oceanic intrusives) during rapid magnetic reversals. Moreover, an estimation of the period

Inference of the movement of the island arcs

The openings of the Japan Sea and the Kuril Basin are inferred to have occurred during the Tertiary. As it is generally accepted that the formation of island arcs is the result of active volcanism caused by the descent of an oceanic plate[16], a tracing of the history of the volcanism and/or the occurrence of the magnetic lineations could reveal the evolution of island arc formation. Unlike the oceanic magnetic lineations, the continental magnetic lineations are not necessarily aligned according to their ages. It seems probable, however, that the igneous activity responsible for the magnetic lineations occurred at closer spacings than are now recognised: for example, we suggest that the Lower Cretaceous intrusion east of north-eastern Honshu must have been closer to the outer margin of eastern Primorye, where another continental

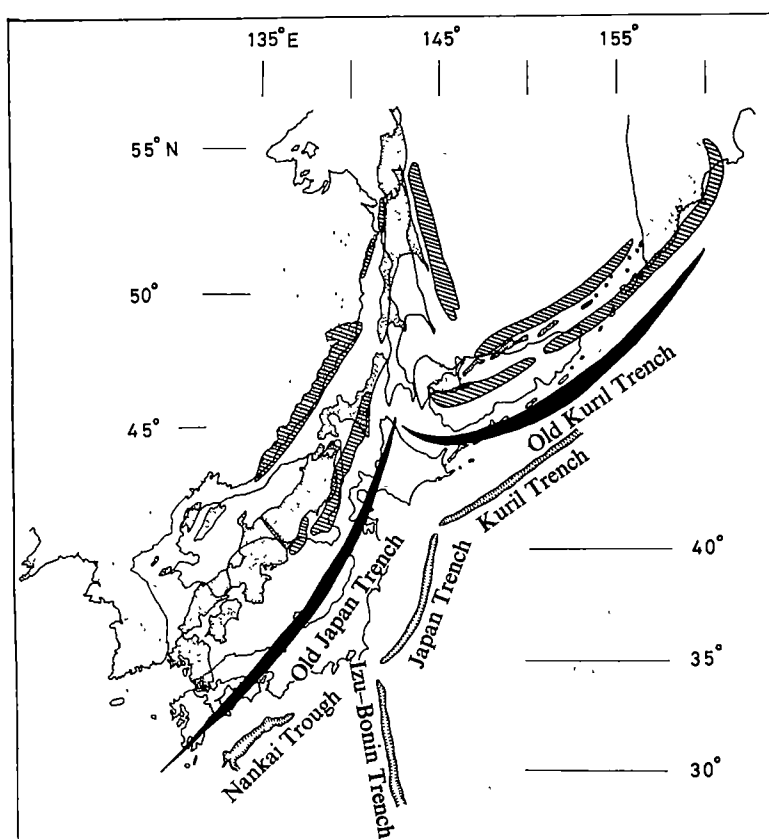

Fig. 5 Reconstruction of a possible feature of the Japan–Sakhalin–Kuril arcs before the Tertiary. Dotted areas, old continent and islands; hatched areas, marked magnetic lineations; Broad solid areas, possible locations of the old Japan and the Kuril trenches.

magnetic lineation is observed. The locations of the volcanic belts may be affected[17] by both the location of the subduction zones and the dip of the descending plates, resulting in a disorderly configuration of the volcanic–orogenic belts with time. We think, however, that the distances between successive (Cordilleran-type) orogenic belts observed at the continental margins are, in most cases, 200–300 km. If this should hold for general cases, the distance of more than 800 km at present recognised between the massifs of northeastern Honshu and the Sikhote-Alin suggests a more recent detachment of Honshu from the eastern Asiatic mainland; that is, a later opening of the Japan Sea. Although this argument requires no magnetic evidence, the documentation of magnetic lineations and their sources has enabled us to generalise the argument to apply to marine areas.

Figure 4 shows the tentative boundaries of continental blocks into which the island arcs can be divided and reconstructed so as to form the eastern Asiatic mainland at a time before the Tertiary. We have used our own criteria of reconstruction.

● We regard parts of an island arc with continental magnetic lineations as a single crustal block.

● Marginal basins such as the Japan Basin, the Yamato Basin and the Kuril Basin are replaced by continental crust.

● The Yamato Bank is regarded as continental crust.

● The central portion of Honshu together with the Izu-Bonin Ridge are excluded because they are very young.

● The Honshu, the western part of Hokkaido, and Sakhalin are treated as a single block because they seem to be connected across the Tsugaru and the Soya Straits, as is verified by seismic[18] and gravity results[19].

● The eastern part of Hokkaido is connected to the block of the Kuril Arc.

● Each block is either translated or rotated in such a way that the continental magnetic lineations become parallel and as close to each other as possible. In this case, north-eastern Honshu turns clockwise, whereas south-western Honshu turns anticlockwise.

Figure 5 shows a reconstruction for the Japan–Sakhalin–Kuril–Kamchatka region. A most significant corollary has been obtained as a result of dividing the Hokkaido district into western and eastern parts. The Hidaka Massif, trending north–south in the middle of Hokkaido, is known as a unique collision-type zone[20] showing a reversed, paired metamorphic belt[21], and it may be accounted for in terms of the collision of two island arcs. The area west of the Hidaka Mountain, that is, the Ishikari zone, is one of the most highly fractured and folded zones in Japan. As seen from the results of the test drilling at the Sorachi region (Fig. 3), the eastern Palaeogene sedimentary layers step over the western portions of the same layers. This suggests that intense folding and fracturing occurred in and after the Palaeogene. Results from seismic refraction surveys (S. Asano *et al.*, unpublished), P-wave travel-time anomalies (T. Moriya *et al.*, unpublished) and electrical conductivity anomalies (Y. Nishida, unpublished) also indicate abrupt changes of crustal thicknesses and depths of conductive layers in the mantle between western and eastern Hokkaido. This evidence suggests that the Hidaka Massif was built when the eastern crust of Hokkaido rode over the western crust during a collision of two island arcs, when the Honshu–Hokkaido–Sakhalin block was drifting south-eastwards, away from eastern Asia, and the Kuril Arc was moving southwards. A convergence of crusts occurred at the present Hidaka Mountain area. The reversed paired metamorphism of the Hidaka region may be regarded as a result of the upheaval and exposure of the crust on the eastern side, which was produced by the igneous activity of the former Kuril subduction zone.

We thank Dr Katsuro Ogawa of the Japan Petroleum Development Corporation for his advice.

Growth inhibition of animal cells by succinylated concanavalin A

Raphael J. Mannino & Max M. Burger

Department of Biochemistry, Biocenter, University of Basel, Klingelbergstrasse 70, CH 4056 Basel, Switzerland

A non-agglutinating lectin preparation, succinyl-con A, inhibits the growth of untransformed 3T3 mouse fibroblasts in a manner that mimics density-dependent growth inhibition. The growth inhibitory interaction between succinyl-con A and cells occurs exclusively during the mitotic and/or early G_1 phase of the cell cycle.

A DIRECT role for the cell surface in the maintenance and regulation of cell growth has been suggested but never convincingly demonstrated. Lectins which bind sugars have been successfully used to examine the composition and properties of that part of the cell surface that is available to the extracellular environment. In a number of cell types a correlation has been shown between saturation density in tissue culture and both agglutinability with lectins[1] and, in defined conditions, tumorigenicity[2]. Several investigations have demonstrated a correlation between the agglutinable surface configuration and growth of both normal and transformed cells[3].

We have reported previously that normal cells during mitosis also exhibit the agglutinable surface configuration and have suggested that this mitotic surface change might be involved in growth regulation[4]. In this report we present evidence that a non-toxic, non-agglutinating lectin preparation interacts with 3T3 mouse fibroblasts during the mitotic phase of the cell cycle and induces a "density-dependent like" growth inhibition.

Growth of 3T3 cells inhibited by succinyl-con A

The enzymatic preparation of non-agglutinating concanavalin A (con A) by protease[5,6] has proved difficult (although a detailed preparative procedure has been described by Evans and Jones[7]) as compared with the succinylation procedure of Gunther *et al.*[8]. A slight modification of that procedure, that is, scaling up the preparation sixfold and introducing affinity chromatography on Sephadex G-50 after the final succinylation, has reduced the contamination by tetrameric con A from approximately 5% to less than 0.1% when assayed by sedimentation in the analytical ultracentrifuge and glycogen precipitation. There were no detectable differences in the growth inhibitory properties of these various succinyl-con A preparations.

Succinyl-con A inhibits the growth of untransformed 3T3 cells in a way that depends on concentration (Fig. 1*a*). The growth inhibition seems to be specific for succinyl-con A since as much as 500 µg ml⁻¹ succinylated bovine serum albumin (succinyl-BSA) has no inhibitory effect on cell growth and, furthermore, since growth inhibition by 500 µg ml⁻¹ succinyl-con A can be prevented (95% that of control) by

10^{-2} M α-methyl-D-mannoside, a hapten specific for con A. Succinyl-con A inhibited cells accumulate in the G_1 phase of the cell cycle (determined by impulse cytophotometry) and show a rate of ³H-thymidine incorporation per cell identical to that of a density inhibited monolayer.

Other experiments suggest that succinyl-con A does not inhibit growth by binding to, and therefore "removing" from the medium a necessary growth factor, but rather that succinyl-con A interacts directly with the cell. First, Dulbecco's modified Eagle's medium preincubated with 500 µg ml⁻¹ succinyl-con A at 37 °C for 24 h, and then filtered by diaflow ultracentrifugation to remove the succinyl-con A before the addition of calf serum, supported growth to the same level as untreated medium. Second, an increase in the serum concentration of the growth medium results in an increase in the final density of both control and succinyl-con A–treated cells. Significantly, however, the percentage of growth inhibition at a given concentration of succinyl-con A is independent of the serum concentration.

Inhibition of growth by succinyl-con A seems to be non-toxic since it is reversible simply by removing the medium containing the succinyl-con A and replacing with fresh medium (Fig. 1*b*). Succinyl-con A–inhibited cells show the same percentage of cells responding to serum pulses with succinyl-con A as control cells show to serum pulses without succinyl-con A. The plating efficiency of cells inhibited by succinyl-con A is similar to that of cells from a density-inhibited monolayer.

It should be noted that although quantitative differences in the growth inhibitory capacity of succinyl-con A can vary as much as twofold when using different cell clones and different succinyl-con A preparations, the qualitative effects are consistent. The data presented here reflect some of our least active succinyl-con A preparations. Some preparations decrease saturation densities to 50% with 200 µg ml⁻¹ succinyl-con A.

Inhibition of growth is dependent on cell density

An interesting aspect of growth inhibition induced by succinyl-con A is that the cell density at which growth ceases is independent of the initial, that is, plating, density (Table 1). It seems that growth inhibition is some function of both succinyl-con A–cell interactions and cell–cell interactions and that succinyl-con A–cell interactions and cell–cell interactions are similar effects which in some way can substitute for one another to inhibit growth.

Succinyl-con A acts only during mitosis and/or early G_1

Synchronously growing 3T3 cells were tested for their susceptibility to succinyl-con A at various times during the

cell cycle (Fig. 2). Even though succinyl-con A may be present from the initiation of a new cell cycle in G_0, through the rest of G_1, S, and G_2, one round of cell division is not inhibited; the cells go through mitosis and come to rest in G_1 (Fig. 2a). Indeed, if succinyl-con A is removed just before mitosis, the cells continue to grow, going through a second round of the cell cycle essentially as if they had never been in the presence of succinyl-con A; succinyl-con A added immediately before the cells enter mitosis, however, causes a cessation of growth following the completion of that mitotic phase.

By adding succinyl-con A to a synchronously growing population of 3T3 cells at various times throughout the mitotic period, it was possible to obtain a more detailed understanding of the inhibition induced by succinyl-con A

Fig. 2 Cell cycle dependence of succinyl-con A–induced growth inhibition. a, 3T3 cells were subcultured into DME + 2% calf serum. When growth had become stationary[37], the medium was replaced with DME + 10% calf serum ± succinyl-con A (500 μg ml⁻¹) and replaced again 23 h later, just before mitosis: ●, control; ■, succinyl-con A at the first medium change, none at the second; □, succinyl-con A at the second medium change; ○, succinyl-con A at both medium changes. b, 3T3 cells from a 2-d-old confluent monolayer were subcultured into DME + 10% calf serum; succinyl-con A (final concentration 500 μg ml⁻¹) was added at various times during the mitotic period; cells at a density indicated by the continuous line (lower curve) at the time of addition of succinyl-con A grew to a corresponding final density indicated by the broken line (upper curve); each point represents three samples counted in duplicate; cell numbers were determined as described in Fig. 1.

Fig. 1 Characteristics of succinyl-con A–induced growth inhibition of 3T3 mouse fibroblasts. 3T3 cells were subcultured into 3.5 cm tissue culture dishes containing Dulbecco's modified Eagle's medium (DME) + 10% calf serum; the medium was changed after 1 and 4 days of growth to DME + 5% calf serum ± succinyl-con A as indicated. Cell numbers were determined using a Coulter counter after removal with a buffered EDTA (0.54 M)-trypsin (0.05%) solution; each point represents duplicate samples counted twice. a, Concentration dependence of succinyl-con A–induced growth inhibition; b, reversibility of growth inhibition. □, control; ○, 250 μg ml⁻¹ succinyl-con A; △, 500 μg ml⁻¹ succinyl-con A; ● and ▲, succinyl-con A removed on d 4 and replaced by fresh medium containing 5% calf serum.

Table 1 Density dependence of succinyl-con A–induced growth inhibition

Initial density (cells cm⁻² × 10⁻⁴)	Final density (cells cm⁻² × 10⁻⁴)	% of control
a Controls (0.15–0.50)	2.80±5%	
0.15	1.90	67.7
0.35	2.01	71.9
0.50	2.14	76.4
b Controls (0.18–0.51)	3.40±5%	
0.18	2.27	66.8
0.35	2.44	71.8
0.51	2.45	72.1

Experimental conditions were as described in Fig. 1; a, Cells grown in DME+4% calf serum +250 μg ml⁻¹ succinyl-con A; b, cells grown in DME + 5% calf serum + 250 μg ml⁻¹ succinyl-con A.

(Fig. 2b). As would be predicted in these conditions if the sensitive period of the cell cycle is mitotis and/or nearly G_1, the final density of a cell population is higher if more cells are allowed to pass through mitosis before the addition of succinyl-con A. The new information obtained from this experiment is that the midpoint of the "final density" curve (upper curve, Fig. 2b) is shifted to a time in the cell cycle that is approximately 1.5 h later than the midpoint of the "mitosis" curve (lower curve, Fig. 2b)—in three separate experiments, each done in triplicate, the shift was between 1.5 and 2 h. These data suggest that the phase of the cell cycle during which cells are sensitive to the inhibitory effects of succinyl-con A may be early in G_1, a time during which previously rounded cells, which have just completed mitosis, are returning to a flat morphology but still retain the "agglutinable" cell surface configuration.

to inhibit the growth of transformed cells by interacting with the cell surface. Two preliminary experiments using succinyl-con A covalently linked to polyacrylamide beads inhibited the growth of 3T3 cells to at least 30%.

Trowbridge and Hilborn[32] have reported that succinyl-con A binding to nearly confluent monolayers of 3T3 and SV3T3 cells is saturated at a concentration of 100 µg ml^{-1} at 0 °C in phosphate buffered saline, and they concluded that this concentration has no appreciable effect on cell growth. A closer examination of their data, however, seems to indicate approximately a 30% inhibition of 3T3 cell growth at 100 µg succinyl-con A ml^{-1}, an inhibition which can be reversed by 50 mM α-methyl-D-mannoside. Our findings that concentrations of succinyl-con A higher than 100 µg ml^{-1} have a marked, specific and non-toxic effect on the growth of 3T3 cells, may not be contradictory to the binding studies of

---

Table 2 Summary of surface characteristics of interphase, mitotic and transformed cells

Surface features*	Interphase cells	Mitotic (and early G_1) cells	Transformed cells
Morphology—scanning electron microscope	Flat and relatively smooth surface	Round with many surface microvilli[18]	Less flat with irregular surface features including microvilli, blebs and/or ruffles[9]
Ease of detachment from substratum	Difficult	Easy	Easy
Electrophoretic mobility	Low	High[13]	High[11,12]
Lectins			
(a) Agglutinability[14]	(a) Low	(a) High	(a) High
(b) Binding of fluorescent labelled lectin[4,15]	(b) Low	(b) Higher	(b) Higher (only some)
Glycoproteins	Completely glycosylated	More fucose and sialic acid containing glycopeptides[17]	Incompletely glycosylated. More fucose and sialic[16] acid containing glycopeptides
Glycolipids			
(a) Forssman antigen reactivity	(a) Low	(a) High[19]	(a) High[18]
(b) Gangliosides (for reviews see refs 3 and 23)	(b) Completely glycosylated or "higher" gangliosides	(b) Not determined	(b) Reduction of "higher" gangliosides—accumulation of precursors
Cell contact dependence[20] of surface galactosyl-transferase activity	Dependent	Independent	Independent
Hynes protein	High levels	Very low levels[22]	Absent[21]
Surface antigens (for reviews see refs 3 and 23)	Relatively few	New antigens appear—some disappear	New antigens appear—some disappear
Virus induced fusion	Low	High[24]	Not determined
Surface bound heparin sulphate	High	Released into medium[26] Low	Low[25]

*Many of these characteristics have been determined for a single or at best only a few cell types. Also, when a particular characteristic has been examined in many cell types the surface changes indicated in this table have at times not been consistently observed.

Implications for growth control

Earlier, using lectins as probes for the examination of the cell surface, we suggested that the cell surface architecture of mitotic cells is similar to that of transformed cells and that this surface configuration might have relevance to growth control[4]. Recent data from several laboratories[3,4,9–26], summarised in Table 2, indicate in greater detail the striking similarity between the surfaces of mitotic and transformed cells. Such a pronounced correlation alone entices one to speculate about a cell surface involvement in the mechanisms regulating cellular proliferation.

There is much circumstantial evidence which suggests that succinyl-con A is exerting its inhibitory effect through specific binding to the cell surface. The vast majority of processes mediated by lectins, for example, receptor site patching and capping[27], cell agglutination, and lymphocyte mitogenesis[28,29], involve the binding of the lectin to the cell surface. Two other preparations, glycolipids obtained from *Salmonella minnesota* R mutants[30] and dextran sulphate polymers[31], have been reported

Trowbridge and Hilborn[32], since we believe that the binding that is important for growth inhibition occurs during mitosis and in culture conditions. Glucose and serum components bind competitively to succinyl-con A (M.M.B., unpublished) requiring, therefore, higher overall concentrations to reach the effective concentration at the cell surface. It is not surprising that the concentration dependence of succinyl-con A-induced growth inhibition does not agree with studies of con A or succinyl-con A binding.

We have also observed that succinyl-con A can reduce the growth of both polyoma and SV101 transformed 3T3 cells. Because the stimulatory effect of serum on cell growth is antagonistic to the inhibitory effect of succinyl-con A, inhibition of transformed cells induced by succinyl-con A is best observed in the presence of low serum concentrations (2–5%). In these conditions we have observed a marked, non-toxic reduction in the growth rate of these transformed cell lines, although we have not yet observed complete inhibition.

Some of the factors regulating the growth of 3T3 cells are shown in Fig. 3. On entering the mitotic phase of the cell

cycle the cells undergo a change in their surface architecture and receive a "go" signal which sends them into another round of the cell cycle. It is possible that a change in the intracellular level of cyclic nucleotides plays a part in this "go" signal[33], but, since there is no convincing evidence that cyclic AMP or cyclic GMP alterations are causally related to growth inhibition and control, many other mechanisms will have to be considered.
Fig. 3 Proposed interrelationships of various factors regulating the growth of 3T3 cells and the involvement of the mitotic cell surface configuration. The "go" signal occurs early in mitosis, perhaps concomitant with the change to the agglutinable state; the "stop" signal must be received before the cells revert back to the non-agglutinable state some time early in G_1. ←→ indicates the period of the cell cycle during which the cells are agglutinable.

When the cell density in the immediate environment of a given cell reaches a certain level, growth stops and the cell accumulates in G_0, a specific part of G_1. Pardee[34] has demonstrated that cells whose growth has been inhibited by high cyclic AMP levels, serum starvation or nutrient starvation, all accumulate at the same point in the cell cycle through a "restriction point" control mechanism. We would hypothesise that cells inhibited by succinyl-con A accumulate at the same point in the cell cycle by the same mechanism.

Cells that have stopped growing and are resting in G_0 can be induced to re-enter the growth cycle by a number of treatments, including serum stimulation, insulin treatment, urea treatment, mild proteolysis and, in the case of succinyl-con A-inhibited cells, removal of succinyl-con A. Serum stimulation, insulin treatment, urea treatment and mild proteolysis all cause the surface membrane to undergo very rapid change to the agglutinable state (Bombik, Bechtel, and M. M. Burger, unpublished, and Weston and Hendricks[35]). If succinyl-con A is added concomitantly with a serum pulse, cell division is not inhibited, even though the agglutinable surface configuration is known to be present (data not shown). This suggests to us that not only is a specific cell surface configuration required for succinyl-con A to exert its inhibitory effect, but also that the particular surface requirements must occur during a specific part of the cell cycle. We suggest therefore that cells are capable of receiving a "stop" signal

only in early G_1, when untransformed cells still exhibit the cell surface configuration detectable by lectin. If growing cells proceed through this period in the cell cycle without receiving a "stop" signal, they are committed both to a complete round of DNA replication and to cell division. Cells which do not receive the "stop" signal accumulate in G_0 but are "past the point of no return". If G_0 cells are stimulated to re-enter the growth cycle, they are unable to receive a "stop" signal, either from succinyl-con A or from high cell density, until they have proceeded through the entire cell cycle, entered mitosis and once again assumed an agglutinable surface configuration.

The biochemical nature of this "stop" signal is unknown, but two distinct types of mechanisms immediately present themselves. First, succinyl-con A could interact with the cell surface producing a generalised membrane effect, that is, an overall change in the cell surface membrane. Stoker[36] has suggested that density-dependent inhibition of growth is the result of a diffusion barrier established when cells grow to high densities; the interaction of succinyl-con A with the cell surface could establish a similar barrier to the diffusion or transport of metabolites essential to growth. Alternatively, succinyl-con A may increase cell surface "stickiness" leading to a decreased mobility after cell–cell collisions and this decreased mobility resulting in growth inhibition (there is no evidence for an increase in the stickiness between cells and substratum).

The second possibility is that succinyl-con A interacts with a specific, unique surface receptor, triggering a series of biochemical events which result in the production of a growth inhibitory "second messenger".

Our data suggest that succinyl-con A interacts with untransformed 3T3 cells during the early G_1 phase of the cell cycle to inhibit growth by a mechanism that, by all the criteria measured so far, seems to be identical to density-dependent inhibition of growth.

Massive black holes in globular clusters?

FOUR X-ray sources have been identified[1,2] with globular star clusters (NGC1851, NGC6441, NGC6624 and M15). These are the first X-ray sources to be optically identified with the oldest component (age $\sim 10^{10}$ yr) of the stellar population of our Galaxy; previous identifications of galactic X-ray sources were mostly with bright, young, Population I stars or with relatively recent supernova remnants. Katz[3], Clark[4] and Canizares and Neighbours[5] have discussed the apparent differences in frequency and population between the globular cluster X-ray sources and other galactic X-ray sources. They have assumed that the X-ray sources in globular clusters are, like the sources identified with Population I stars, binary stars in which a normal companion transfers mass on to a collapsed star, thereby producing X rays.

Here we suggest that the globular cluster X-ray sources may be a very different phenomenon from the previously studied binary X-ray sources. In particular, we suggest that the observed X-ray emission in globular clusters may be caused by accretion of gas on to a massive black hole at the centre of the cluster. This suggestion is consistent with theories of stellar and cluster evolution and with previous observations of globular clusters. Both the theory of cluster core collapse and some observational consequences of black holes in globular clusters have been widely discussed (see refs 6–8 and references therein).

We assume a central massive object accreting at the rate $\dot{M}_{acc}$ and converting rest mass to X rays (2–10 keV) with efficiency ε as follows:

$$L_x = (\varepsilon/0.1)\,(\dot{M}_{acc}/10^{-9}M_\odot/\text{yr}) \times 10^{37}\ \text{erg s}^{-1} \qquad (1)$$

We have considered two possible sources of accretional mass. Normal stellar evolution in an old system will release

$$\dot{M}_{gas} \approx 10^{-11} M_\odot\ \text{yr}^{-1}\,(L_{cl}/L_\odot) \qquad (2)$$

or about $10^{-6} M_\odot\ \text{yr}^{-1}$ (with an uncertainty of at least an order of magnitude) in the entire cluster. If this gas is produced

Fig. 1 Globular cluster central escape velocity and central relaxation time from data of Peterson and King[10]. Circled points are known X-ray sources. Arrow indicates change for M15 if its core radius has been overestimated by a factor of 1.5. Clusters above hatched regions are expected to be tightly enough bound to retain gas.
with a velocity of 25 km s^{-1} (characteristic of planetary nebula expansion rates) it will be retained in some, but not all, of the globular clusters (Fig. 1). Dimensional arguments suggest[9] that $T \geq T_{BB} \equiv [GMM_{acc}/8\pi R^3\sigma]^{\frac{1}{4}}$ (where R is the distance from the black hole), which implies that the X-ray efficiency could be appreciable. Massive black holes may also be able to acquire the gas required for accretion directly by tidally disrupting stars which approach too closely. A very rough analysis of this problem gives a rate proportional to $M_H^{4/3} \rho_c^{\frac{1}{2}} r_c^{-1}$ where M_H is the mass of the hole and (ρ_c, r_c) are the cluster core density and radius. Taking observed numbers for these parameters from Peterson and King[10] (with $|M/L|_{cluster}$ assumed 1), we find $\dot{M}_{dis} \lesssim 10^{-9}(M_{BH}/10^3 M_\odot)^{4/3} M_\odot$ yr^{-1}. This rate is much less than that given by normal stellar evolution but it is produced in the immediate vicinity of the hole and might be accreted with greater efficiency.

If the gas is streaming through the centre of the cluster with a characteristic velocity, v_{gas}, then it will be captured[11] at a characteristic radius

$$R_c = GM_{BH}/v_{gas}^2 \simeq 2 \times 10^{13}\ \text{cm}\ (M_{BH}/M_\odot)\,((25\ \text{km s}^{-1})/v_{gas})^2$$

where M_{BH} is the mass of the black hole. At somewhat larger distances from the black hole, the characteristic density would be

$$n_{gas} \sim (\pi R_c^2 v_{gas} m_{proton})^{-1}(dM/dt)_{accretion} \qquad (3)$$

or

$$n_{gas} \sim 15\ \text{cm}^{-3}(L_x/10^{37}\text{erg s}^{-1})(0.1/\varepsilon) \times \\ \times (10^3 M_\odot/M_{BH})^2 (v_{gas}/(25\ \text{km s}^{-1})^3$$

For a gas with this typical density, 15 cm^{-3}, the total mass, if it were spread uniformly over the central R_{pc} of the cluster, is only $M_{gas} \sim 2 M_\odot R_{pc}^3$. There may also be additional gas not in the cluster core, part of which will eventually fall into the cluster centre.

There is a minimum black hole mass that can produce the observed X-ray intensity, since the mass of gas accumulated in the cluster is less than or equal to $\dot{M}_{gas} t_{encounter}$, where $t_{encounter}$ is the time since the last passage through the galactic disk. The accretion rate, $\dot{M}_{accr} = 4\pi R_c^2 \rho_c v_c$, is proportional to M_{BH}^2 and must be equal to $(L_x/c^2\varepsilon)$. The pressure scale height for the gas heated by X rays is ~ 1 pc for typical parameters which implies that much of the gas is unavailable for accretion. Assuming an approximate isobaric relationship, $\rho_c T_c = \rho_{core} T_{core}$ (where the cluster core is typically ~ 0.4 pc) and inserting the maximum allowable value for ρ_{core} ($\sim 0.1 \dot{M}_{gas} t_{encounter}$/volume of the core) in equation (3), one finds a minimum black hole mass:

$$M_{BH} \geq 10^{2.5} M_\odot \left| \left(\frac{0.1}{\varepsilon}\right)\left(\frac{L_x}{10^{37}\text{erg s}^{-1}}\right)\left(\frac{v_{gas}}{25\ \text{km s}^{-1}}\right)^3 \left(\frac{T_{core}}{0.1 T_c}\right) \right|^{1/2}$$

(4)

Also because of the limited amount of gas available near the black hole, the X-ray luminosity is, for typical parameters, only $L_x \sim 10^{32.5}$ erg s^{-1} $(M_{BH}/M_\odot)^2 (M_{gas}/10 M_\odot)(\varepsilon/0.1)$, much less than the Eddington limit for the masses we consider (but

comparable with the observed luminosities). Normal cluster stars could have retained close white dwarf companions and accretion onto these might give $L_x \leq 10^{36}$ erg s^{-1}, but could not explain a bright source such as NGC6624.

Most of the gas will be ionised by ultraviolet radiation from the stars in the cluster[12] as well as by the X radiation from the vicinity of the black hole. The total mass of ionised gas may be too small to produce any observable absorption in the X-ray spectrum or to have been detected in the most sensitive radio searches conducted so far (typical good upper limits for H II are $\sim 30M_\odot$ for several clusters[13]; there are stronger limits[14,15] for H I). The most sensitive possible radio searches for thermal bremsstrahlung from H II gas in the X-ray clusters would be of interest.

We note that a search for Balmer emission lines in the cluster centres would also be of great interest. The expected total flux from the ionised gas is $\sim 2 \times 10^{-13}$ erg cm^{-2} s^{-1} (distance/ 10 kpc)$^{-2}$ in H_β. This is much less than the continuum optical emission from a typical X-ray globular cluster even when one takes into account only that small part of the cluster continuum that would lie within a reasonably small slit. Nevertheless one might, with good luck and excellent technique, be able to place significant limits on, or detect, the postulated gas. Typical expected equivalent widths are of the order of 10^{-2}Å in an H_β line of ~ 1 Å width and depend on, among other things, the slit size used and the unknown spatial extent of the ionised gas. The usually strong forbidden emission lines, such as O II λ3727 and O III λ5007, should be missing (at least near the centre of the cluster) because the typical ionisation stage in the presence of the X-ray flux would be higher.

The model considered here leads to two unambiguous predictions. First, the X-ray emission should be point-like and located at the centre of the globular cluster. Second, there should be no eclipses, orbital or spin periods observed in the X rays (although periods $\sim 0.1(M_{BH}/10^3M_\odot)$ s, from particles orbiting near the black hole, might occur in some circumstances). One can show that a pair of massive black holes, or a swarm of lower mass condensed objects, would have evolved dynamically to a single central rotating black hole through many-body interactions and gravitational radiation. One might hope that the observable star distribution and velocity dispersion near the centre of a globular cluster X-ray source are somewhat different than in other clusters. But for an integrable star density $\rho \propto r^{-\alpha}$ near the hole (Peebles[8] gives $\alpha = 9/4$), one finds a fractional increase in the luminosity of only

$$\Delta L/L_{core} \approx [\alpha/(3-\alpha)](M_{BH}/M_{core})^3 \qquad (5)$$

which is probably not observable unless $M_{BH} \leq 0.2M_{core}$. The detection[15] of 10.2 μm radiation from the centre region of M15 suggests that something unusual is indeed happening in the core of this X-ray cluster. Further infrared measurements of globular clusters are of the greatest possible interest (especially since a large fraction of the total luminosity in the X-ray clusters could be in this spectral region).

Finally we must consider the reasons why, on our model, only a small fraction ($\sim$ a few per cent) of the globular clusters in our Galaxy are X-ray sources. There are at least three obvious possibilities. First, only a moderate fraction of the clusters are bound tightly enough to retain gas. Second, the gas production rate may be sporadic. Third, it may be that only a few of the globular clusters have evolved dynamically far enough to have formed massive black holes in their centres. From a detailed investigation of Spitzer's Monte-Carlo simulation[6,7], it seems that core collapse occurs at a time $\tau \simeq 10^2\tau_c$ from the moment when the central relaxation time is measured to be τ_c. Using data from Peterson and King[10], we show the deduced values of τ_c in Fig. 1. The clusters to the right of the hatched region should collapse within the next 12×10^9 yr. They are correspondingly the best candidates for clusters

within which core collapse has already occurred. It is interesting to note that the two X-ray clusters (shown by circles in Fig. 1) in the well-studied group of Peterson and King lie in the relatively small region having short core relaxation time and large central escape velocity.

Anisotropic redshift distribution for compact galaxies with absorption spectra

RUBIN et al.[1] have found that in one hemisphere of the sky ScI galaxies with $14.0 \leq m \leq 15.0$ have a mean velocity $1,365 \pm 200$ km s^{-1} larger than in the other hemisphere. Anisotropies, corresponding to this, have also been found for brightest cluster galaxies, supernovae (T.J., G. Le Denmat, M.M., J. C. Pecker and J.P.V., unpublished and ref. 2), and Markarian galaxies (H.K. and M.M., unpublished). Here we present a similar result for absorption line compact galaxies.

Zwicky's catalogue[3] has been used, selecting from it the compacts with measured redshift and absorption spectra. Since absorption line and emission line compact galaxies have different (m, z) relations these cannot be sampled together, and the number of the latter is rather small for a separate analysis. In absorption spectra also, those with [O II] λ 3727 emission were included in the case that the compact is not blue (most emission objects are blue), since this line is a common component in the normal spectrum of galaxies. Galaxies which are not compact but only have a compact core or some other compact part were not included, for the same reason as the emission objects. In the case of pairs only one component was included in order not to have double weight for these objects, a minority of the sample. The brighter one was taken if m_p is given for each component but if not we corrected m_T by $+ 0.75$ mag as an estimate of the individual m_p. If one of the components was indicated to be brighter than the other, a half correction, 0.37 mag, was applied to m_T. The mean velocity was used in the case of pairs. The cosec law with coefficient 0.25 mag was used for correction of galactic absorption, and galaxies with $|b^{II}| < 20°$ were excluded. The sky was divided into two regions, as was done by Rubin et al.[1] (Fig. 1). As in the earlier studies, the smallest velocities $V < 3,000$ km s^{-1} (only one compact) were not considered. The Hubble modulus $HM = \log V - 0.2m$ is the suitable parameter for this kind of study since it is purely observational and reflects best individual absolute luminosities or, alternatively, individual V/r values in a sample.
Fig. 1 Distribution of compact galaxies with known redshifts and absorption spectra on the sky. Circles are for galaxies with $m_c \leqslant 15.0$ and triangles for those with $m_c > 15.0$. Filled symbols show galaxies with $\delta HM > 0$ and open symbols those with $\delta HM < 0$ where $\delta HM = HM - \langle HM \rangle$, the mean value $\langle HM \rangle$ being calculated separately for intervals $m_c \leqslant 15.0$ and $m_c > 15$ 0. The full curve from upper left to lower right is the borderline between the two regions of sky. The other full curve shows the galactic equator. The areas included between dashed lines and the galactic equator are those of exceptionally high and low absorption, denoted by HA and LA, respectively. The latter have been transformed from the map in galactic coordinates given by Holmberg[4], and show areas where absorption deviates from the law $A = 0.25 \, \mathrm{cosec} |b^{II}|$ by ± 0.15 mag or more.

Considering the interval of corrected magnitude $14.0 < m_c \leqslant 15.0$, we obtain for the mean HM in region I the value $\langle HM \rangle_I = 0.88 \pm 0.10$ (5 galaxies) and for region II $\langle HM \rangle_{II} = 1.12 \pm 0.04$ (10 galaxies). For the galaxies with $m_c \leqslant 15.0$ (all have $m_c > 13.0$), $\langle HM \rangle_I = 0.93 \pm 0.07$ (7 galaxies) and $\langle HM \rangle_{II} = 1.10 \pm 0.04$ (15 galaxies). For the galaxies with $m_c > 15.0$ (all have $m_c < 18.0$), $\langle HM \rangle_I = 0.82 \pm 0.04$ (34 galaxies) and $\langle HM \rangle_{II} = 0.87 \pm 0.03$ (27 galaxies). For the whole interval $13.0 < m_c < 18.0$, $\langle HM \rangle_I = 0.84 \pm 0.04$ (41 galaxies) and $\langle HM \rangle_{II} = 0.95 \pm 0.03$ (42 galaxies). In the different m_c intervals the differences in $\langle HM \rangle$ between regions II and I are 0.24 ± 0.107, 0.17 ± 0.089, 0.05 ± 0.050 and 0.11 ± 0.050, respectively. These are significant at 2.24 σ, 1.91 σ, 1.00 σ, and 2.20 σ levels, corresponding to chance probabilities 0.020, 0.035, 0.170 and 0.015. The mean difference of velocities of objects in region II and I is $3,400 \pm 1,850$ km s^{-1} for $m_c < 15$ and $700 \pm 1,400$ km s^{-1} for $m_c > 15$. For $m_c < 15.0$ the average values $\langle m_c \rangle = 14.3$ and $\langle V \rangle = 8,650$ km s^{-1} are valid. For $m_c < 15.0$, $\langle m_c \rangle = 16.1$ and $\langle V \rangle = 12,700$ km s^{-1}.

From the differences in $\langle HM \rangle$ one finds that compact galaxies with absorption spectra show a significant redshift anisotropy in the same direction as previously found[1,2]. The anisotropy decreases from the maximum at $14 < m_c \leqslant 15$, especially towards fainter magnitudes. This favours the view that the effect is not due to galactic or intergalactic absorption since absorption would also cause an apparent anisotropy at large distances. This view is supported also by Fig. 1 which gives the distribution of the galaxies on the sky and information on individual HM and shows the regions of exceptionally high and exceptionally low absorption as given by Holmberg[4]. Small HM are not associated with areas of high absorption and large HM with areas of low absorption, as would be expected for an apparent anisotropy attributable to absorbing clouds[5].

Pulsar glitches and restlessness as a hard superfluidity phenomenon

SEVERAL pulsars[1] have "restless" behaviour of the period similar to that of the Crab and Vela pulsars[2] which has been explained[3] as due to "microquakes" in the crust. A glitch has also been observed[1] with, possibly, a new type of signature, in PSR1508+55. We suggest that these phenomena can be explained at least equally well by noisiness in the rate of creep of vorticity through the neutron superfluid in the crust, in almost precise analogy to the well known noisy behaviour of flux creep in hard superconducting magnets[4]. In addition, even the macroglitches, especially those in the Vela pulsar, may be caused by the catastrophic release of pinned vorticity.

The lower crust of the neutron star contains fat nuclei bathed in a neutron Fermi gas which is almost surely superfluid[5]. The discussions we have found of this superfluid do not observe that its T_c and energy gap will at most densities be determined by the proximity effect from those of the neutron superfluid inside the nuclei, since the outer Fermi gas is from 1/2 to 1/10 as dense and will probably have a smaller intrinsic gap (see Fig. 1 and ref. 6). The neutrons inside the nuclei will contribute to some extent to the neutron ρ_s, since their phases are coupled by Josephson tunnelling through the surrounding gas even if that gas is not intrinsically superfluid. T_cs and Δs in the 1/2 to 2 MeV range are reasonable, as is a $\rho_s \sim 10^{12}$–10^{14} g cm^{-3}. Because of the tunnelling effect the correlation length will usually be essentially the internuclear distance: the substance is a very hard Type II superfluid[4].

As Pines pointed out, pinning of the quantised vortex lines which are implied by the rotation of the superfluid,

$$n_{\text{vertices}} = 2m\Omega/h \sim 10^{4-5} \, cm^{-2} \qquad (1)$$

can occur in the crust; they will to some extent be pinned by the regular lattice, since the coherence length is never much greater than the internuclear distance, and even more so by cracks, grain boundaries and other features such as are surely created by quakes. We visualise that vortex lines can slide along lattice planes relatively easily, and are blocked especially severely at these features. Experience with pinning in the analogous hard superconductors suggests that the breaking strength of this vorticity pinning may be surprisingly high. To estimate the pinning strength we estimate the energy of a vortex core as

$$E_{\text{core}}/\text{length} = (\Delta^2/E_F)(k_F^3 \xi^2)$$

and the force per unit length exertable by pinning is this

divided by the distance over which the force acts,

$$F/\text{length} = (\Delta^2/E_F)k_F^3\xi \times p \approx k_F^2\Delta p \simeq 10^{20}p \text{ dyne cm}^{-1} \quad (2)$$

where p is a "pinning probability" factor < 1 describing the fractional density and effectiveness of pinning centres (comparable to the factor p in refs 7 and 8). This force is also of the order one would estimate for the strength of the lattice itself, so that vorticity may fracture the structure rather than
Fig. 1 Proton and neutron density distributions occurring along an axis joining the centres of two unit cells. a, $^{180}Zr_{40}$ with $n_b = 2.79 \times 10^{35}$; b, $^{320}Zr_{40}$ with $n_b = 8.79 \times 10^{35}$; c, $^{1100}Sn_{50}$ with $n_b = 5.77 \times 10^{36}$; d, $^{1800}Sn_{50}$ with $n_b = 2.04 \times 10^{37}$; e, $^{1500}Zr_{40}$ with $n_b = 4.75 \times 10^{37}$; f, $^{982}Ge_{32}$ with $n_b = 7.89 \times 10^{37}$.

unpin from the lattice. Equation (2) must be equated with the Bernoulli force on a vortex:

$$F = (h/2m)\rho v \text{ per unit length} \quad (3)$$

to obtain a critical relative velocity of crust and neutron superfluid at a given point

$$v_c \simeq (2m/h\rho)k_F^2\Delta p$$
$$\simeq 10^8 p \text{ cm s}^{-1}$$

If the difference in angular frequency $\Omega_c - \Omega_n$ is $\Delta\Omega$,

$$(\Delta\Omega)_{crit} = v_c/R \simeq 50p \text{ s}^{-1} \quad (4)$$

Thus even if p is very small there can be strong pinning forces. If it is the actual lattice which pins, p will not be particularly small, $\sim 1/10$–$1/100$ or so. But equation (4) indicates such large values of $(\Delta\Omega)_{crit}$ that we must expect that in most stars the superfluid in the crust is effectively pinned and does not change its Ω, and that in others it will be pinned in some regions and at some times. The former are probably the majority of pulsars which show quiet behaviour[1].

Here we give some suggestions, necessarily rather speculative, as to the actual physics of superfluidity in the pulsar. In the first place, the frictional force suggested by Baym and Pines due to electron scattering on vortex cores is far too small to unpin the vortices; that force may be estimated to be

$$F_{friction} = \rho R\Delta\omega/\tau \text{ per unit volume}$$

$$\lesssim 10^5 \text{ dyne cm}^{-3}$$

where τ is the spin-up decay time of order months introduced by Baym *et al.* If the Bernoulli force due to relative motion of

crust and superfluid is not larger than indicated by equation (2) the vortices stay at fixed positions in the crust rather than flowing with the superfluid as they do in a normal soft superfluid. The Bernoulli force is strong enough that the vortex lines in the core fluid will probably not move with the crust, but will flow with the core superfluid. This must lead to complicated dynamics at the interface; our suspicion is that a turbulent boundary layer will form which breaks up all phase coherence at the crust–core boundary. The theory of these phenomena has been discussed by Greenstein[9]. As he points out, the viscosity due to the turbulence can be of the same order as that due to electron scattering and can be the cause of spin-up. The turbulence and pinning seem likely to damp out any Tkachenko waves or similar collective modes of the vortex lattice. In any case, vorticity need not be perfectly conserved in passing from core to crust, as one might have thought at first.

Thus the dynamics of the core and of spin-ups is little affected. But what does appear here is a second, decoupled, superfluid which in the case of light stars may be a fair fraction $(10^{-2}$–$10^{-1})$ of the neutron superfluid. This crustal superfluid may lag behind the slowing angular velocity of the crust by some cycles per second. The slowing of this superfluid must necessarily take place by the very noisy process of vorticity creep, with concomitant "vorticity jumps" which occur when a particular group of pinning centres become too weak, and may be thought of as the superfluid vortex lattice's equivalent of crustquakes. The reason why these processes will be noisy is that once vortex lines start to move, there is no adequate source of damping to soak up the rotational kinetic energy which is thereby deposited in the vortex lattice. Whether the vortex lattice or the crust itself fractures is not relevant; in either case the event must continue until the stress is relieved.

A second, somewhat independent consequence of superfluid dynamics in neutron stars is the fact that even in the "canonical" view the superfluid never rotates with the same angular velocity as the pulses or the crust, but lags behind by a relative amount τ/T (T is the "lifetime" parameter of ref. 1). The relative lag of crustal superfluid is much greater. It is not obvious that in all cases these angular velocities should be coaxial; this should only be the case if the forces are always simply drag forces and have no couple perpendicular to the axis. In an accreting star such as Her X-1 the accreting matter can exert non-axial couples, and one would not expect Ω_c and Ω_n to be parallel. This can lead to further complications in the dynamics of such systems.

One may estimate that the amount of energy stored in the vortex cores is only $\lesssim 10^{-12}$ of the total rotational energy of the neutron star: using the estimate already given one cannot assume much more than 10^{30} erg in a shell 1 km deep at a radius of 10 km. Nonetheless the associated events may, just as in a superconducting magnet, be much larger than the energy involved in pinning. It is the stored relative rotational energy which is relevant, which can easily be 10^{41} erg. This can be larger than the elastic energy which is responsible for quakes, while the magnitude of strength parameters is similar; thus these events will tend to be larger and more frequent, at least in light stars, than quakes. Thus any of the observed events seem explicable on this basis. We do, however, consider it likely that at least crust quakes will occur as well, and that sometimes the two can occur together.

Superfluidity and hydrodynamic instability mechanisms previously suggested for glitches[9,10] are quite distinct from the present one, and, we believe, less likely. A matter of some importance is that the suggestions for laboratory simulation of the rotating superfluid star become even more meaningful, but that the correct model should have a porous outer layer: the model should be a Reppy superfluid gyroscope[11] with a hole in the centre, not simply a ball of superfluid. Such experiments could help with the vexing question of the boundary layer viscosity and the continuity of vortex lines from core to crust. It would be interesting to study vorticity jumps in such a structure as well as precessional motions.

One of us (P.W.A.) thanks the Technion in Haifa for hospitality and M. A. Alpar for discussions.

Giant olivine chondrule as a possible later-stage product in the nebula

ABUNDANCES of trace elements, in particular, of rare-earth elements (REE) in the Allende Chondrite and its inclusions have attracted increasing attention from geochemists[1-4]. Based on the abundance characteristics of major elements and trace elements (including REE), Martin and Mason[3] distinguished four distinct groups among the aggregates and chondrules of the Allende Meteorite. We report here on the presence of an olivine chondrule in Allende with REE abundance features quite different from those of any inclusions previously reported.

By chance, we found an extraordinarily large chondrule in Allende (Fig. 1). It measured 7 mm in diameter and appeared light grey with darker coloration towards the margin. In general, the olivine chondrules in this meteorite are only a few millimetres or less in size: previously Tanaka and Masuda[1] studied Allende olivine chondrules which had diameters of about 3 mm. Chemical analysis and X-ray diffraction indicate that the composition of this giant chondrule is much closer to pure olivine than that of the olivine chondrules analysed before[4]. Chemical

Fig. 1 A giant olivine chondrule in the Allende Chondrite. Scale bar, 1 cm.
Fig. 2 Chondrite normalised pattern using the Leedey Chondrite as standard. *a*, REE and other elements from the giant olivine chondrule in the Allende Chondrite; *b–e*, other inclusions in the same meteorite; *b*, olivine chondrule; *c*, Ca, Al-rich chondrule; *d*, inclusion G pink; *e*, whole rock.

analyses by Nakamura *et al.* (unpublished) suggest that the material studied here is almost pure olivine (Fo$_{79}$) with perhaps 1.5% feldspathic or glass component.

About 120 mg of the sample were used for determination of REE, Ba, Sr and Rb abundance using a stable isotope dilution technique; Ca and Al abundance were determined by atomic absorption spectroscopy. Analyses are presented in Table 1 and Fig. 2. (For the normalisation of REE abundances, the Leedey chondrite[5] is used as a reference.) The abundances of common REE in the giant olivine chondrule are 40 times lower than those in ordinary olivine chondrules, and there are positive anomalies for Ce and Eu. Although a Yb anomaly is often observed in meteorites[1-3,6], it is not present in this sample. The abundance of Ba is 4 times as high as the reference value, whereas that of Sr is about half the reference value and that of Ca is as low as one-tenth of the corresponding chondritic reference abundance. There is no comparable fractionation among alkaline earth metals in ordinary olivine chondrules[1,3]. The extent of the fractionation of Ba, Sr and Ca may be more or less related to the absolute levels of abundance of common REE and also, presumably, to the size of the olivine chondrule. In addition, a considerable depletion of Al also distinguishes the giant olivine chondrule from ordinary olivine chondrules[1]. In the giant chondrule the contents of Na and K (Nakamura *et al.*, unpublished) are about one-third to one-fifth of those in the Allende bulk sample[2]. Thus, the olivine chondrule studied here is extraordinary not only in size, but also in its chemical features.

It is conceivable that the material constituting the giant olivine chondrule came into being in conditions which favoured

Table 1 Abundances of REE, Ba, Sr, Rb (p.p.m.), Ca and Al (%) in a giant olivine chondrule from the Allende Chondrite

La	0.021	Gd	0.0122	Ba	18.0
Ce	0.32	Dy	0.0140	Sr	2.44
Nd	0.029	Er	0.0098	Rb	0.67
Sm	0.0098	Yb	0.0097	Ca	0.129
Eu	0.0082	Lu	0.00152	Al	0.33

the precipitation of material with an olivine composition only, though these conditions would not have precluded the precipitation of material which gave rise to other chemically different types of chondrules. The very low abundances of common REE imply that these refractory elements had been depleted from the gaseous phase of the nebula by the time that the material represented by this giant olivine chondrule had formed.

The positive Ce and Eu anomalies can be accounted for by the relatively high pressures of the oxides of Ce and Eu[7,8]. Oxides of Ba, Ce, and Eu are more volatile than those of other common REE, and the order of volatility of the metal oxides is Ba > Ce > Eu (ref. 9).

It is worth considering the low content of Rb, one of the comparatively volatile elements. It is possible that although the giant olivine chondrule formed as a later-stage product in the nebula, the temperature at that stage was not low enough to condense the alkali metals in the chondrule.

The characteristics observed in the chondrule are not entirely in line with earlier thermodynamic studies of REE fractionation[10]. (Note the presence of a positive large Ce anomaly, the absence of a positive Yb anomaly, and a mutually unfractionated, flat pattern for common REE from La to Lu.)

In any case, we suggest that the giant olivine chondrule is extremely pure material which could have formed at specific temperature ranges. Broadly speaking, this chondrule of wholly new type may be complementary to Ca, Al-rich aggregate with unfractionated REE (ref. 3) though, in detail, additional components are required.

Heat flow and incipient rifting in the Central African Plateau

EIGHT new heat flow measurements from Precambrian sites in the Republic of Zambia (Fig. 1) range between 55 and 76 mW m^{-2}. Compared with the mean for Precambrian provinces elsewhere, these results are anomalously high by some 50%. This heat flow anomaly persists after taking into account radioactive heat generation of near surface rocks,

and therefore may be interpreted as indicating the presence of anomalously warm material only a few tens of kilometres beneath the Earth's crust. We believe these observations support the hypothesis of an incipient arm of the East African rift system as proposed by Fairhead and Girdler[1,2] and suggest that it may extend into the central African plateau to at least 16°S.

Temperature surveys were made with thermistor probes in more than thirty boreholes distributed over the eight sites, usually several weeks to several months after drilling had been completed. Depths of measurement range from 160 to 1,200 m. Thermal conductivities of solid rock disks sampled from drill cores at 10 to 20 m intervals were subsequently determined on a conventional divided bar apparatus. Heat flow values were then calculated as the product of the least squares geothermal gradient and the harmonic mean conductivity. Mean heat flow values for the sites are given in Table 1.

The results of radioactive heat production measurements on aggregate samples of core chips from several of the sites are also presented in Table 1. No heat production values were obtained for the Ichimpe and Luanshya sites where the boreholes penetrate mainly sedimentary sequences.

In interpreting continental heat flow results it is important to ascertain the tectonic and thermal history of the region. Apart from limited areas covered by Karroo (Permian–Jurassic) sedimentary and volcanic rocks and Kalahari (Pleistocene–Holocene) sands, most of Zambia consists of pre-Silurian, mainly Precambrian, rocks[3] (Fig. 1). The last tectono-thermal event recorded in Zambia is the Damaran–Katangan (Pan-African) episode, which is represented at the northern heat flow sites by isotopic ages of 520 ± 50 Myr, and at the southern sites by ages of 730 ± 50 Myr, (ref. 3). One site, Mkushi, has been unaffected since the earlier Kibaran orogeny and has been dated[4] at >1,635 Myr.

Figure 2 is a graph of continental heat flow as function of age of most recent tectonic mobilisation, after Polyak and Smirnov[5], who identified in some detail the clear trend of diminishing heat flow with increasing age of tectonic province. Also shown in Fig. 2 is the mean value of 66 mW m^{-2} for the eight Zambian sites, plotted collectively at 700 Myr. The Zambian surface heat flow is anomalously high by about 30 mW m^{-2} compared with Precambrian shields elsewhere.

Large surface heat flow can result merely from enhanced radiogenic heat production in the upper few kilometres of the crust. We have compared our heat production measurements with all available data from other Precambrian shields and conclude that enhanced heat production can account for no more than one half of the 30 mW m^{-2} surface anomaly. We therefore infer a heat flux anomaly of at least 15 mW m^{-2} originating in the lower crust or below. Furthermore, as lower crustal and upper mantle rocks are depleted in heat producing isotopes by a factor of five to ten relative to upper crustal rocks, it is unlikely that the source of the residual heat flow anomaly is radiogenic. A more probable source is an anomalous zone of elevated temperatures at depth resulting from an intrusion or from some thermal process in the asthenosphere.

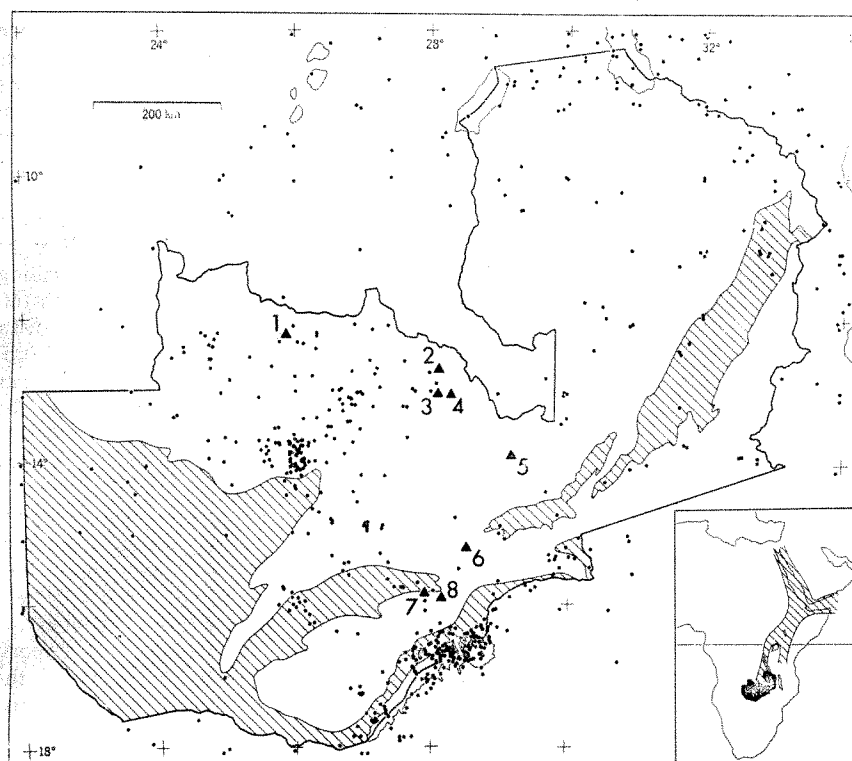
We consider two interpretive models to explain the observed heat flow anomaly. The first involves the computation of surface heat flow in time following a sudden increase in temperature at a given depth. In the plate tectonic model this may correspond to the lithosphere coming to rest over an asthenospheric hot spot or a convective upwelling. If such an event happened during the Miocene[6], plausible solutions restrict the depth of the disturbance to less than 60 km; at greater depths an unacceptably large temperature perturbation is required to produce the observed surface anomaly. A second model involves a temperature perturbation which is spatially


Fig. 1 Location map of the Republic of Zambia showing heat flow sites (▲), earthquake epicentres (•), Precambrian (unshaded) and post Pan-African (shaded) terrains. Epicentres drawn from International Seismological Centre (Edinburgh) Regional Catalogue of Earthquakes, 1965–70. Inset map shows the zone of inferred lithospheric thinning from Fairhead and Girdler[2].

periodic at the base of a moving slab, corresponding to the lithosphere moving over an array of hot and cold spots below. In this model the solution is an upward propagating thermal wave which is both attenuated and phase shifted at the surface. The magnitude of the observed heat flow anomaly places restrictions on both the depth to the temperature perturbations and the velocity at which the plate moves over them. To satisfy the observed surface heat flow anomaly, calculations utilising this model require that the anomalous zone be less than 60 km deep, and also that the lithosphere be moving less than 2 cm yr^{-1} relative to the source pattern.

Arguments can be made for the applicability of either model. It remains unclear whether the central African region of the African plate is at rest in a hot spot frame of reference[6], or is moving slowly northwards[7]. In either case the source of the thermal anomaly cannot lie deeper than 60 km, and if the source is an intrusion from, or the upper boundary of, the asthenosphere, it represents a considerable penetration into or thinning of the continental lithosphere.

Lithospheric thinning has already been proposed by Fairhead and Girdler for the tectonically active East African rift system, to explain slow seismic wave propogation and

high attenuation, and large negative Bouguer gravity anomalies. They map a single zone of thinned lithosphere southward from Ethiopia almost to the Equator where it bifurcates into the eastern and western rifts (Fig. 1, inset). The southernmost part of the western zone departs from Lake Tanganyika, and strikes SSW across the topographically unbroken central African plateau, to approximately 12°S.

How far south does this lithospheric thinning extend? The region of high heat flow in Zambia lies directly on the extension of the western arm of the anomalous zone. We therefore believe the geothermal measurements argue convincingly for an extension of the zone of lithospheric thinning southward through western Zambia, at least to 16°S. Some additional support for this interpretation is drawn from the distribution of seismicity in Zambia (Fig. 1). Two clusters of epicentres are apparent; one in the middle Zambezi Valley, a Mesozoic rift structure which has been seismically active since the impoundment of Lake Kariba, and a second in west-central Zambia. The occurrence of earthquakes in the latter region is curiously uncorrelated with any obvious geological or topographic feature, but does lie nearly wholly within the region of high heat flow and conjectured thin lithosphere. The presence of earthquakes

Table 1 Heat flow and heat production data

	Site	Latitude	Longitude	Heat production* (μW m^{-3})	Heat flow (mW m^{-2})
1	Lumwana	12° 15'S	25° 51'E	2.5	55±8
2	Ichimpe	12° 44'S	28° 07'E		74±4
3	Lumpuma	13° 05'S	28° 03'E	1.8	65±4
4	Luanshya	13° 05'S	28° 19'E		76±4
5	Mkushi	13° 55'S	29° 12'E	1.9	62±2
6	Chalalobuka	15° 13'S	28° 33'E	2.3	66±3
7	Lubombo	15° 49'S	27° 55'E	3.6	71±2
8	Munali Hills	15° 55'S	28° 08'E	1.0	64±4

*Heat production determinations are subject to measurement uncertainties of about 1%. Uncertainties arising from sampling are limited to less than 15% by assembling aggregate samples from throughout each borehole.
Fig. 2 Mean heat flow from eight Zambian sites superimposed on plot of heat flow against age of tectogenesis after Polyak and Smirnov[5]. Tectonic provinces include: PcS, Precambrian shield; PcP, Precambrian platform; C, Caledonian folding; H, Hercynian folding; M, Mesozoic folding; CM, Cainozoic miogeosyncline. Shaded ellipse represents standard error of the mean heat flow; vertical bar and open ellipse represent standard deviation.

in the anomalous zone suggests that this region, like the mature rifts in East Africa, is dynamic and responding to contemporary tectonic stress.

Further work is required to delineate the boundaries and continuity of this important geophysical anomaly. But our heat flow results to date and the seismicity of western Zambia lend strength to the hypothesis of incipient rifting in the central African plateau.

Structure of turbulent boundary layers at maximum drag reduction

WE describe here the results of a preliminary study on boundary layers carried out with an aqueous equimolar solution of cetyltrimethylammonium bromide (CTAB) and 1-naphthol at a total concentration of 508 parts per million

(p.p.m.). Dilute, high polymer solutions in pipe flow can produce a drag reduction which is bounded by a limiting asymptote curve[1], and micellar solutions of CTAB-1-naphthol exhibit drag reduction described by the same asymptote[2,3]. Measurements of the velocity profiles of the micellar solution across a pipe diameter show fairly good agreement with the ultimate profile deduced[4] from pipe friction results. This particular drag reducing solution is suitable for experiments in closed loop systems because of its resistance to permanent mechanical degradation.

The measurements reported here were taken at the base of a small flume using the pulsed hydrogen bubble technique for flow visualisation and qualitative measurement. Essentially, the method is that developed by Kline et al.[5,6].

The working section of the flume was 0.28 m wide by 0.20 m deep and was fed from a large stilling chamber, through a contraction, to produce a uniform flow. The circulation was induced by a variable speed centrifugal

Table 1 Summary of near-wall observations

		Water	CTAB-1-naphthol solution	
U_∞	(m s^{-1})	0.365	0.350	0.250
u^*	(m s^{-1})	0.017	0.013	0.0077
v	(m^2 s^{-1})	1.130×10^{-6}	1.280×10^{-6}	1.270×10^{-6}
F	(burst s^{-1} m^{-1})	290	20	9.0
λ	(m)	0.0073	0.037	0.050
λ^+	$(= \lambda u^*/v)$	115	375	300
T_b	$(= 1/F\lambda)$	0.475	1.35	2.22

pump. A boundary-layer trip wire, 1 mm in diameter, was placed across the floor of the channel at the entry end. The stainless steel cathode wire from which the hydrogen bubbles were liberated was 0.05 mm in diameter and was mounted transversely to the flow on a traversing mechanism situated 0.64 m downstream from the boundary-layer trip wire. Flow patterns were recorded on video tape for subsequent analysis.

Mean velocity profiles in dimensionless form are shown in Fig. 1. The wall shear stress, for the micellar solution was determined from the near-wall velocity profile slope. The water test did not provide sufficient data points within the extremely thin viscous sublayer and in that case a modified Clauser procedure was used to determine the wall shear-stress[5]. Experimental results from the micellar

Fig. 1 Boundary layer velocity profiles: $U^+ = u/u^*$; $Y^+ = yu^*/v$ (where u is the mean velocity at distance y from the wall; $u^* = (\tau_w/\rho)^{\frac{1}{2}}$; $\tau_w =$ wall shear stress; $\rho =$ fluid density; $v =$ kinematic viscosity. ●, Water, ($u^* = 0.017$ m s^{-1}); ⊙, CTAB-1-naphthol solution ($u^* = 0.013$ m s^{-1}); ×, CTAB-1-naphthol solution ($u^* = 0.0077$ m s^{-1}). a, $U^+ = 11.7 \ln Y^+ - 17.0$; b, $U^+ = 2.44 \ln Y^+ + 4.9$; c, free-stream values.
solution seem to be adequately described by Virk's limiting-velocity profile model[4].

The bulk of turbulence production is associated[6] with low speed streaks which originate near the wall in the viscous sublayer and with their subsequent eruption or 'bursting'. From a study of the video records, measurements of the mean transverse spacing of the streaks, λ, the burst frequency per unit span, F, and the time between bursts, T_b, were determined (Table 1). The results obtained with water show fairly good agreement with previous investigations[5-7]. In addition to producing a large friction reduction the micellar solution showed a large increase in the transverse spacing of the streaks and a large reduction in the burst frequency. These changes are more dramatic than those found by previous investigators who used less effective drag reducing solutions[7]. Although the time between bursts T_b, is increased, the value still seems to correlate with the friction velocity, u^*, on the same unique line as that found with water and other polymeric solutions (ref. 7, and B. U. Achia and D. W. Thompson, unpublished).

The shape of the mean velocity profile supports the use of similarity laws for the prediction of boundary-layer skin friction in conditions of maximum drag reduction.

Carbon fibre pH-sensitive electrode

VARIOUS forms of carbon have been considered as possible indicator electrodes for use in locating end points in acid-base titrations; these forms have included graphite[1], vitreous or glassy carbon[2] and pyrolytic graphite[3]. Microelectrodes can be used in titrations of small volumes, such as those found in biological cells[4], and certain forms of carbon such as glassy carbon, are exceptionally resistant to oral and tissue fluids[5]. We have examined the electrical potential response of a single carbon fibre to pH changes in aqueous electrolyte solutions.

The potential of a carbon fibre electrode 1 cm long and 7–8 μm in diameter, sealed into a Pyrex glass tube with epoxy resin, was measured against a saturated calomel reference electrode in various buffer solutions in the pH range 1–13, using a Corning EEL 109 digital pH meter used in its millivolt measuring mode. We found a linear relationship between the potential and pH, with a negative slope of about 50 mV per pH unit at room temperature (about 20 °C). The potential in any given buffer, such as 0.05 M potassium hydrogen phthalate, is stable to within 1 mV, within measuring times of a few minutes. Larger variations in potential (and also the slope factor) were, however, observed when the same electrode was examined over a period of weeks; this implies that a carbon-fibre pH electrode of this kind must be calibrated on each day of its use.

The potential of a carbon fibre pH electrode is unaffected by the presence or absence of dissolved oxygen: the same potential was recorded even when pure nitrogen was bubbled through the buffer solution. A small negative shift in potential was, however, observed with temperature increase (about 0.6 mV °C^{-1}). The potential of a carbon fibre electrode is affected by the presence in solutions of strong oxidants such as bromine and cerium(IV) and also by the presence of reductants, such as arsenic(III).

We believe that the observed pH response of the carbon fibre electrode may be caused by the possible ionisation of carboxylic acid groups formed on the surface of carbon by surface reactions with atmospheric oxygen[6,7].

Electrostatic energy of columbite/ixiolite

A KNOWLEDGE of the crystal structure of an inorganic compound and the appropriate ionic charges is usually sufficient to allow the calculation of the electrostatic energy[1-3]. A more difficult situation is found in crystals where some or all of the cations are disordered so that on the average a particular cation site is occupied by two or more cations with different charges. Very accurate crystal structure refinements, often including refinement of site occupancies, can give a good description of the nature of the disorder and the average composition of each cation site. The electrostatic energy can then be calculated using the average ionic charges on each of the disordered sites. Such an approach has been used to compare the stabilities of ordered and disordered structures of pyrrhotite[4,5] and some complex niobium and tantalum oxides[6]. There seems no theoretical justification for the use of average cation charges for the calculation of the potential energy of a disordered crystal so such calculations must be treated with caution.

Consider a hypothetical crystal structure in which two different cations with different ionic charges occupy four cation sites such that, in the completely ordered arrangement, three are occupied by one ion (A) and the other site contains the second type of ion (B). The ordered arrangement then may be represented by the symbols AAAB. A completely disordered version of this structure determined from a diffraction experiment would be (as indicated above) $3/4A + 1/4B$ for each of the four cation sites. But on the level of an individual unit cell, each cation can be either A or B only and not some fictitious average ion. There are four unique arrangements of 3A and 1B over four sites, namely AAAB, AABA, ABAA and BAAA and the electrostatic energy of each of these ordered arrangements may be calculated by standard procedures. As we do not know how to calculate correctly the energy of the disordered structure, we must deal with what is available; the energies of all the possible ordered arrangements of the cations.

The mineral columbite, $MnNb_2O_6$, offers a good example. In the orthorhombic unit cell are 12 cation sites occupied by 8 Nb and 4 Mn. The charges on the sites in the ordered structure (columbite) are either 5 or 2 and in the disordered structure (ixiolite) the average cation charge on all sites is 4. Barker and Graham[6] have calculated the electrostatic energy of columbite and ixiolite and find that the ordered arrangement is very much more stable than the disordered. This is difficult to reconcile
Fig. 1 A histogram of the electrostatic energies of the 495 possible arrangements of 8 Nb and 4 Mn ions in the unit cell of columbite. The "ordered charge" corresponds to the known distribution of the cations, "average charge" represents the energy computed for a structure with average ionic charges (+4) on all cations and "average energy" is the average of all 495 energies.

with the well known tendency of natural columbites to be partially or totally disordered. I suggest that this apparent inconsistency between observation and the calculated energies is due to the incorrectness of the assumption that an electrostatic energy based on average cation charges is an accurate measure of the energy of a real disordered structure.

There are 495 different ways of distributing 8 Nb and 4 Mn over 12 cation sites and the electrostatic energy of each of these structures was calculated along with the energy of the structure containing cations of average charge (+4). The resulting energies are plotted as a histogram (Fig. 1). The calculated energies range from $-9,758$ to $-8,421$ kcalorie mol^{-1} with an average value of $-9,356$ kcalorie mol^{-1} which is greater than the energy, $-9,201$ kcalorie mol^{-1}, for the average charge structure. The largest energy is for the structure of columbite.

Figure 1 shows that many possible arrangements of cations have energies not very different from that for the arrangement in columbite. For example, there are 84 cation arrangements (17%) within 158 kcalorie mol^{-1} of the columbite structure. The spread in energies is probably much less than that shown in Fig. 1 because the geometry of the crystal structure used for the calculations and particularly the sizes of the oxygen polyhedra coordinating the cations are optimum only for the cation distribution in columbite. If the crystal structure of each of the 495 cation arrangements could be optimised, the energy of each would probably increase, the net effect being to compress the histogram towards the position of the columbite structure.

Assuming that the value of $-9,201$ kcalorie mol^{-1} is the true energy of the disordered structure, the question "why does one find disordered crystals in nature when the columbite structure is much more stable?" should be recast in the light of Fig. 1 to "why does one find disordered crystals in nature when hundreds of different ordered arrangements of cations are more stable?" The only reasonable answer is that $-9,201$ kcalorie mol^{-1} is not the correct energy of the disordered structure. Therefore, the method of calculating the energy of the disordered structure is in error and one cannot in general determine whether a particular structure is liable or not to cation disorder by comparing average cation charge energies with ordered charge energies.

I propose that the way to make such a judgment is to calculate the electrostatic energy for all possible combinations of cations as done here for columbite. If there are ordered cation

arrangements with energies close to that of the normal ordered structure, then one would expect that partial or complete disorder of the cations would occur because the existence of other cation distributions with not very different energies indicates that the ions can occupy different sites with relatively little penalty in terms of potential energy. But if there is a large energy gap between the normal structure and other possible ordered distributions, one would not expect to find structures with cation disorder. Figure 1 shows that columbite falls into the first category and so disorder is not surprising. Exactly what energy gap is needed for a structure to have only an ordered arrangement of cations is not known but estimates could be obtained by study of appropriate crystal structures as done here for columbite.

I thank Dr S. Weller for comments. This work was supported by the National Research Council.

Radiocarbon dates for the Pennine Mesolithic

WE present here a series of ten new radiocarbon dates obtained from charcoal samples collected (1) from sites around Marsden, Yorkshire (Table 1), and formerly stored in the Tolson Memorial Museum, Huddersfield, and (2) from samples collected on upland Pennine sites during the past two years. A single new date from Marsh Benham, Berkshire, is also presented. This short series of dates has some bearing on the relative ages of what Buckley[1] termed the 'broad blade' and 'narrow blade' industries.

The radiocarbon dating of Pennine Mesolithic sites poses several problems. The sizes of the sites vary considerably and there are indications that some may have been occupied for perhaps only a single season, whereas others show signs of lengthy occupation or of having been revisited several times. Datable materials are, however, scarce or absent in all cases, no doubt because of the exposed nature of the upland sites and the constant erosion by high winds and driving rain at these altitudes. The time which elapsed between the abandonment of the sites and their protection by peat formation is unknown, but it was sufficient for most of the datable artefacts to have been destroyed. In the few instances in which charcoal or partially burnt wood has survived in hearths, there is a possibility that contamination has occurred by mineral particles of calcium carbonate and by the down-soaking of humic solutions from the overlying blanket-bog peat. Though these two sources of contamination would have opposite effects on apparent ages they can be eliminated by successive treatments with dilute solutions of hydrochloric acid and alkali. The latter treatment also dissolves a black shiny bituminous substance which sometimes separates from peat and may be confused with charcoal.

Measurements have been made using proportional gas counters with plastic scintillation anticoincidence shielding within a lead castle. Dates have been calculated using the 'Libby half life' of 5,568 yr for the ^{14}C isotope. Where

Table 1 Radiocarbon dates from Mesolithic sites

* Broad blade site.
† March Hill type site.
‡ Rod dominated type site.

samples were small, the technique of dilution with inert carbon dioxide was used. No attempt has been made to calibrate the figures with the bristlecone pine, dendro-chronology curve.

The 'broad blade' industry, now recognised from some 140 locations on the Pennines, was dominated by the manufacture of simple, obliquely blunted points (often retouched on the leading edge) with rare, elongated isosceles triangles and convex-backed blades with a mean width of 8–10 mm. Mellars[2] has pointed out the Maglemosian affinities of this group, comparing the content of these upland sites with Deepcar, Thatcham, Colne Valley[3] and Broxbourne 102 (ref. 4). Confirmation of this purely intuitive correlation is suggested by both computer cluster analysis and a date of 7,615 ± 350b.c. for Lominot site III, "one of two round emplacements"[5] on the eastern side of a hill excavated in 1924 and 1925. That excavation produced 34 microliths[3], end scrapers and awls, 90.9% of the raw material being white flint originating from south-eastern Yorkshire and northern Lincolnshire. Similar material has also been found on other typologically identical sites from both upland and lowland areas[6]. The date agrees, within one standard deviation, with determinations from the Zone V/VI part of the occupation in the swamp-marl at Thatcham Site I/V (ref. 7), (Q-677: 6,830 ± 200b.c.; Q-650: 7,720 ± 160b.c.; and Q-652: 7,550 ± 160b.c.) and with a date of 7,350 ± 150b.c. from a new Maglemosian site, with bone, at Marsh Benham.

The second early site to be dated, Warcock Hill South, differs markedly from the other upland 'broad blade' sites in the shortness and relative width of its microliths, the absence of convex-backed points and points retouched on the leading edge, and in its raw materials. Excavated from "within a space of four square yards" (F. Buckley, private printing, 1924) the industry was based on transparent grey, black and honey coloured flints, identical to those of Star Carr and Flixton Site I (ref. 8) with which industries it bears the closest visual similarity, and with which it links statistically, forming a cluster distinct from that which includes Lominot Site III, Deepcar, Marsh Benham and Thatcham sites I/V–III. Pieces of white flint and chert now housed in the Tolson Museum are clearly of post excavation mixing as both of these raw materials are specifically stated by Buckley (unpublished) to have been absent. The radiocarbon date of 7,260 ± 340b.c. agrees, within the statistical uncertainty, with those from Star Carr (Q-14: 7,607 ± 210b.c.; and C-353: 8,217 ± 560b.c.; and 6,858 ± 490b.c.)[8,10] and could lie, on the basis of the Scaleby Moss diagram, within Zone V, the V/VI boundary here being dated Q-161: 7,059 ± 194b.c. (ref. 10). Warcock Hill South might thus be the contemporary of Flixton Site I, the occupation of which continued into Zone V[11].

Sites of Buckley's 'narrow blade' type break down into three distinct groups, each distinguished both typologically and by the presence and proportions of the raw materials used. The largest group, which we here term the 'March Hill' type industry, is dominated by small scalene triangles, normally less than 5 mm wide, and is known from both upland and lowland locations. These lie on the Pennine and Cleveland moors and also occur in northern Lincolnshire and along the Durham[12,13] and Cumberland[14] coasts. The second group is dominated by straight rod-like microliths blunted along one or two sides. These are known only from high ground on the Pennines and Clevelands. The third group, with many small thomboids, is known in northern England only from two sites, both undated: White Hill North and Red Ratcher on the southern Pennines. The first two groups are confined to northern England, and all three lack the inversely retouched leaf and hollow based (Horsham) points characteristic of the sites in south-eastern England.

Radiocarbon dates for the 'March Hill' type industry cover some three millennia. The earliest, 6,660 ± 110b.c., from Warcock Hill Site III, comes from measurements on charcoal from three 'cooking pits' excavated by Buckley and connected with a circular concentration of chert chippings including only a small number of triangular microliths. The date is identical to one from the Broomhead V Site (6,620 ± 110b.c.)[15,16] and together these represent the earliest known dates for the late Mesolithic type industries in Britain, agreeing closely with the earliest appearance of small scalene triangles in mainland Europe. That the later dates are correct and not too young is hinted at by the presence of a 'March Hill' type industry in terrestrial deposits on top of the early postglacial raised beach at Eskmeals, Cumberland[14], which accumulated, on the evidence from Silverdale Moss, at about 4,640BC (Q-260: 6,590 ± 144b.p.)[17]. Furthermore, the consistency of the two dates from March Hill Site II, measured on charcoal from either the same, or a pair of cooking pits (Buckley's note-books are ambiguous) suggests that the dates are correct.

Some charcoal was excavated from a hearth (Rocher Moss South 2), in an eastwards extension of Rocher Moss South 1 (ref. 18). The site also yielded 35 straight, rod-like microliths, but there were no scalene triangles of the March Hill type. This charcoal gave a date of 3,880 ± 100b.c. (Q-1190), which would, along with a date associated with a similar but smaller industry at Dunford Bridge Site B (3,430 ± 80b.c.; Q-799)[15,16] suggest a date late in the Mesolithic for 'Rod microlithic' industries of this type.

No comment has so far been made of a site at Stump Cross, Grassington[19] where in 1955 24 flint artefacts were found with charred wood, stratified in mud in a rock cleft. Of five pollen samples associated with the flint, four were representative of the classical pollen zone VIIa which reached 30 cm above it and one represented the early part of Zone VIIa and the Boreal–Atlantic, VIIa/VI transition, 5 cm below it. Measurements of the wood yielded a date (Q-141) of 6,500 ± 310b.c. (refs 10 and 20), which is about 1,000 yr earlier than the usually accepted date of this boundary. Possibly, ancient wood had been blown or washed into the pool and became incorporated into the mud. The two rod-like microliths could derive from either a 'March Hill' or 'Rod' type of industry. The mention[19], however, of the occurrence of chert as a raw material, which, in fact, never appears in industries of the 'Rod' type, suggests that the few artefacts recovered belong to the former, rather than the latter, group.

This radiocarbon evidence from the Pennines indicates conclusively that simple 'broad blade' microlithic industries identical to those of Thatcham and Star Carr precede 'narrow blade' (sometimes termed 'Sauveterrian') industries with small scalene triangles and rod-like microliths, which appear just before the middle of the seventh millennium

BC and persist probably until the end of the Mesolithic. Identical successions can be demonstrated on the basis of radiocarbon dating, stratigraphy and pollen analysis, for the valleys of the Lea, Colne and Kennet in south-eastern England, and also for North Wales, whereas the Zone VIIa pollen age for a group of small scalene triangles from Cock Heads, Glaisdale (J. Bartlett, personal communication) contrasts with the Zone IV and V attribution of the Star Carr and Flixton sites in the nearby Vale of Pickering.

We thank Mr J. A. Gilks, of the Tolson Memorial Museum, for access to the Buckley collection and the drawing books in his care, and for allowing samples of charcoal to be removed for radiocarbon dating. Thanks are also due to Dr W. P. Stonehouse, Mr J. Davies, Miss P. Beswick and T. G. Manby.

Possible mechanisms of corona discharge involved in biogenesis

ELECTRIC discharges are very efficient[1] in synthesising amino acids and other organic compounds in conditions which simulate the atmosphere of the primitive Earth. Consequently, they may have been of considerable importance in the origin of life. Corona emission from pointed objects is probably[1] the most effective form of electric discharge involved in prebiotic synthesis. Clearly, coronae occurring in the vicinity of the oceans would be of particular importance, but even though land surfaces generally possess features of sufficient irregularity to permit corona emission in naturally occurring electric fields of moderate strength, it is not obvious that suitable protuberances exist at the ocean surface.

I present here a brief description of experiments which reveal three processes by which coronae can be produced at or near the ocean surface. Two of these processes—the splashing of raindrops in water and the collision of pairs of raindrops—have already been reported[2,3] and are mentioned here only in view of their possible relevance to prebiotic synthesis. The third mechanism is concerned with bubble-bursting.

When a drop falls into water and splashes, a jet of liquid is ejected vertically upwards. It has a diameter close to that of the original drop and may rise several centimetres above the water surface. If such splashing events occur in the presence of an electric field, E, the jet is pulled out further by the field, and when E achieves a critical value, E_c, the tip of the jet becomes pointed and a corona is emitted[2]. The value of E_c decreases as the drop radius, R, increases, and for drops of $R = 3$ mm, about the largest size existing in natural rainfall, $E_c \approx 180$ kV m^{-1}.

When a pair of raindrops collide, the shapes which they assume before separating depend on their sizes, the velocity of impact, and the obliquity of the collision. In some recent experiments[3] a pair of drops, of radii 2.7 mm and 0.65 mm respectively, were brought into collision with a relative velocity of 5.8 m s^{-1} (which is close to the value appropriate to raindrops of this size falling at terminal velocity in the lower atmosphere). The collisions occurred in the presence of a vertical electric field and corona discharges could be detected. When the drops underwent glancing collisions a long filament of liquid was drawn out between them as they separated. In these circumstances, with the field parallel to the filament, conditions were particularly conducive to the production of coronae, and values of $E_c \approx 250$ kV m^{-1} were obtained.

Air forced into the oceans by wave motion or precipitation rises to the surface in the form of bubbles. When a bubble bursts at the surface a jet of liquid rises at high velocity from the bottom of the bubble crater[4] and achieves a height of several millimetres before ejecting a number of drops. It seems possible that the tip of the jet formed when a bubble bursts would provide an effective site for corona emission. Bubbles have been produced by passing air through a tube with a fine capillary tip immersed in water filling a square plastic vessel 0.25 m wide and 0.05 m deep. The bubbles rose to the surface near the centre of the vessel and burst in the presence of a vertical electric field. A reversible polarity, 0–30 kV voltage supply was used to apply a potential difference between the water surface and a smoothed, circular electrode of diameter 0.18 m horizontally mounted centrally above it. The electrode spacing could be varied but was maintained at 0.04 m for the majority of the experiments. Generally, the water was connected to the high voltage supply, the vessel standing on an insulating block. The upper electrode was effectively earthed through an oscilloscope used to monitor the discharges. In other experiments the voltage supply was connected to the upper electrode, or bubbles were allowed to rise about 0.15 m before reaching the water surface. Precautions were taken to ensure that the corona detected was associated with bubble-bursting and not with some spurious process. With the bubble supply switched on, the field was increased slowly until the oscilloscope indicated the occurrence of a corona, which was generally audible. Having thus established a rough value of E_c, observations were made in more detail for values of E around this estimated threshold.

The experiments conducted so far show that corona discharges can occur when bubbles burst at a water surface in fields down to 260 kV m^{-1}. The measured values of E_c are independent of the polarity of the electric field and of the electrode spacing once it is more than about 0.02 m. The independence from polarity is to be expected, in view of earlier experiments[2,5] concerned with coronae resulting from other mechanisms of the disruption of a water surface. A more detailed investigation of the variation of E_c with bubble size, the charges transferred during the emissions and the mechanics of bubble-bursting in electric fields, will follow.

The three processes by which corona discharges may occur in the vicinity of the ocean surface—drop splashing, bubble bursting and raindrop collisions—are all determined by the production of points at a liquid surface and are not significantly affected by the purity of the water or the

presence of trace gases in the air: this has been confirmed experimentally, some measurements having been made using seawater. All these processes require the presence of strong fields associated with thunderclouds. A full investigation of the coronae resulting from raindrop collisions and bubble bursting has yet to be made but it seems likely that the minimum values of E_c for all three processes are in the region of $200 kV m^{-1}$. Such values are known to exist within rainshafts and at the surface of the Earth below thunderstorms. The frequency of occurrence of thunderstorms over the Earth is extremely high—of the order of $100 s^{-1}$. As the most generally accepted mechanisms of thundercloud electrification depend entirely on the basic physical properties of water and ice, it is likely that a similar frequency of occurrence existed in the primitive atmosphere of the Earth. Although present meteorological knowledge does not enable an estimation of the relative importance of the three processes of corona discharge, it seems quite probable that one or more of them could have been primarily responsible for biogenesis.

Heavy metal release from plants into the atmosphere

INDUSTRIAL activity has been assumed to be largely responsible for the heavy metal content of atmospheric particulates[1]. We have obtained, however, laboratory evidence that higher plants may naturally contribute to the heavy metal composition of the atmosphere. Experiments with radioisotopes have shown that plants are capable of releasing from their foliage a small fraction of the total amount of several elements originally absorbed by their roots. The mechanism giving rise to the release process is as yet not fully understood but seems to be associated with submicron particles. In this way plants could generate local biogeochemical provinces in the atmosphere and reflect underlying geochemical anomalies. Moreover, this

process could also be responsible for the general enrichment of certain heavy metals in the atmosphere relative to the soil and may partly explain the surprising chemical uniformity of atmospheric particulates[1].

The ability of plants to absorb and translocate heavy metals is established[2]. It is also very likely that plants are capable of generating particulate matter in the atmosphere. Went[3] was able to show a very strong correlation between airborne submicron particles and density of vegetation. He suggested that these aerosols were derived from condensation of volatile organic material released from the leaves. On the other hand there is also evidence that fine wax particles can be readily lost from the surface of many plants[4] and that these too could serve as candidates for the formation of particles.

The aim of the experiments reported here was to explore the possibility that heavy metals may be dispersed into the atmosphere by way of a mechanism involving particulate loss from leaves. We report results mainly obtained using radioactive Zn, but several other elements including Pb and Cu have also been studied. Small pea plants (Pisum sativum) were normally used, although broad bean (Vicia faba) and pine tree seedlings (Pinus sylvestrus) have also been used. Plants were grown in liquid culture[5] containing ^{65}Zn (Radiochemical Centre, Amersham, as $ZnCl_2$; specific activity $0.9 mCi mg^{-1}$). When the plants were fully labelled with the radioisotope they were transferred to perspex chambers consisting of foliage and root compartments divided by split diaphragms. The roots were sealed off from the upper chamber using Silastic 738RTV placed around that part of the stem passing through the aperture in the diaphragm. Clean dry air was passed through the chambers at known flow rates and the outgoing air monitored for radioactivity.

Preliminary experiments indicated that radioactive Zn was being released from the plants into the air stream passing through the chamber. Controls were conducted on plants after removing their foliage by cutting at a point on the stem just above the sealed aperture. In these conditions no radioactivity was detected in the outgoing air stream. Studies with a Casella cascade impactor demonstrated that the main Zn-carrying components were associated with submicron particles. For this reason in most experiments the outgoing air was passed through first a Millipore filter ($0.22 \mu m$ pore size) and then a cold finger trap (solid CO_2 and methylated spirit). Radioactivity on the filter and in the frozen water vapour in the cold finger trap (after drying down on planchets) was assayed using a Nuclear Chicago gas flow counter. In most of our experiments the radioactivity given off from the plants was collected in the cold finger condensates and not on the membrane filters. Although the cold finger would tend to trap volatile

Table 1 Release of Zn from leaves of *Pisum sativum*

External concentration (p.p.m.)	Condition	Average Zn level in leaves (p.p.m fresh weight)	Zn release (pg h^{-1} cm^{-2})	Water transpired (ng h^{-1} cm^{-2})	Zn/water ($\times 10^{-12}$)
0.001	Light	7×10^{-4}	0.08	10.0	8.0
	Dark		0.06	6.6	9.1
0.01	Light	5×10^{-2}	0.72	11.6	62
	Dark		0.38	9.0	42
0.1	Light	0.1	4.50	7.0	643
	Dark		2.26	5.6	404
1.0	Light	0.9	21.00	10.6	1,980
	Dark		4.50	8.6	523

Plants were grown in liquid culture medium containing $0.9 mCi$ ^{65}Zn per mg Zn until fully labelled. Illumination was by white light from an incandescent source at an intensity of $100 W m^{-2}$. Temperature $25 \pm 2 °C$. Air in foliage chamber was exchanged every minute. ^{65}Zn released from the plants was detected only in the cold finger trap (see text) and no radioactivity was found in outlet air for the control experiments. Rates of Zn release are expressed in terms of leaf surface area and computed from 4 h sampling times.

organic compounds released from the plant it also acts as a very efficient trap for submicron particles as shown by studies with a condensation nuclei counter. The trapping of particles by this method almost certainly results from diffusiophoresis[6] (the Facy effect[7]) brought about by the development of partial pressure gradients associated with water condensation.

Table 1 gives the results of an experiment with pea plants exposed to external Zn levels in the range 0.001–1.0 p.p.m. In this experiment the amount of Zn released increased with increasing external levels of this element and was enhanced by illumination. In general the clearest evidence of Zn release was usually seen under growing conditions and required the plants to be fully labelled with radiotracer. The quantity of Zn given off, however, was variable and on several occasions only a small amount of the element was released even when the plants were grown at relatively high Zn levels. Although Zn release occurred

agent. Of all the metals we have investigated (Pb, Cu, Hg and Mn) all can be released to varying degrees from the leaves by the above petroleum ether or water treatment.

Evidence that Aitken-sized particles are released from plants, under the experimental conditions used have come from electron microscopy studies. A thermal precipitator with a reciprocating head was connected to the outlet of the chamber and any particles released from the plant which passed through the Millipore filter were deposited on a collector grid which had been covered with formvar film and coated with a layer of carbon. Electron microscopy indicated that needle-like particles up to 2,000 Å long and 300 Å wide had been given off from pea plants.

As yet it is not clear whether these particles are associated with the heavy metal release but they do resemble the wax rodlets which occur on many leaf surfaces including the leaves of peas. The occurrence of these small wax crystalline rodlets on the leaf surface is variable

Table 2 Release of ^{65}Zn from *Vicia faba* growing in unlabelled and labelled solutions after preloading with ^{65}Zn

External Zn concentration (p.p.m.)	Average Zn level in leaves (p.p.m. fresh weight)	Amount of Zn and water released from prelabelled plants in unlabelled solution over 6 h								Amount of Zn and water released from plants when reintroduced to labelled solution	
		Sample 1		Sample 2		Sample 3		Sample 4		Sample 5	
		Zn	Water	Zn	Water	Zn	Water	Zn	Water	Zn	Water
1.0	1.45	0.96	13.6	0.40	18.4	0	17.2	0	17.6	4.8	12.0
10.0	22.5	10.8	19.2	7.0	24.4	2.24	27.2	1.72	27.2	20.4	15.6

Samples 1–4 were obtained with plants fully labelled with ^{65}Zn but having their roots in an inactive culture medium. Sample 5 was obtained after reintroducing the roots to a medium containing ^{65}Zn. Daily samples were collected over 6 h so that there was an 18 h gap between sampling. In the case of sample 5 the 18 h period was used to preincubate the plants in radioactive solutions. Sampling was carried out under illumination conditions and in between sampling the plants were exposed to the atmosphere and taken through a day–night cycle. Except for a change in specific activity to 0.09 mCi per mg Zn for the 10 p.p.m. treatment the conditions were the same as for Table 1. Zn and water lost from the plants over the 6 h are expressed in pg cm^{-2} and mg cm^{-2}, respectively.

simultaneously with water loss from the plants there was no obvious quantitative association. There was, however, a requirement that the plants were continuously fed with ^{65}Zn. Table 2 shows that when a fully labelled plant was placed in a culture solution not containing ^{65}Zn, there was a decrease in the ^{65}Zn released even though there would have been little or no change in the ^{65}Zn level in the leaves. Replacement of the plant in the radioactive solution re-established the release process. The release mechanism seems to involve a small Zn pool in the leaf, and the remaining Zn in the leaf is not easily exchanged into this pool. Essentially similar results have been obtained with Cu and Pb but the experiments were more difficult, partly because of variability in the effect and partly because of the relatively low levels of these elements in the leaves. For example, with Pb, levels in the leaves and the outgoing air were reduced by 10 to 50 times of that recorded with Zn when the external levels of these elements were the same (for example, 1 p.p.m.).

The above experiments suggest that the release of ^{65}Zn is associated with submicron particles in the Aitken range. A possible source for these could be small particles of epicuticular wax which occur on the leaf surface and which can easily be removed by certain stress conditions such as leaf expansion[8]. Moorby and Squire[9] tentatively suggested that the loss of these waxes may be responsible for the disappearance of ^{89}Sr from leaves which had been surface-contaminated with radioisotope, an explanation also adopted by others[10]. We have checked to see if the ^{65}Zn absorbed by the roots of our plants is translocated to the vicinity of the leaf surface. Both mild wax extraction procedures[11] and leaching experiments[12] indicate that ^{65}Zn was present near the leaf surface. Approximately 0.22 p.p.m. Zn was detected in a crude wax extraction with petroleum ether from leaves collected from pea plants grown in 1 p.p.m. Zn and under the same conditions about 50 pg Zn per cm^2 leaf surface could be leached with distilled water at pH 6.0, containing 0.1% Tween 20 as a wetting

depending on many factors[4] and could account for the variability observed with the metal release. An alternative explanation for the release could be the production of airborne salt crystals generated by diffusiophoresis associated with rapid transpiration[6]. At this stage we have no positive evidence for either process but the quantitative relationship between heavy metal released and water transpired was highly variable.

Although the rate of metal released is small compared with the total metal content of the leaf it is possible that the release mechanism could give rise to anomalous levels of certain elements in the atmosphere. With a soil water level of Zn at 1 p.p.m. our experiments indicate that the rate of loss of Zn from leaf surfaces can be about 20 pg h^{-1} cm^{-2}. Under these conditions 1 cm^2 leaf surface would contain in the region of 6 ng Zn. Accepting an average leaf area index of 5 (ref. 13) then the rate of Zn release from vegetation to the atmosphere would be 1.0 μg h^{-1} m^{-2}. Such release could, together with human activities, give rise to general heavy metal loadings in the atmosphere. Moreover, our results support those of Curtin *et al.*[14], who reported the release of metals, including Zn, from conifers growing on mineralised soils. Whether the metal-rich particles would normally remain in the Aitken size range in the atmosphere is not yet known but aggregation under the influence of sunlight[3] and cohesion with larger particulates may well occur.

Conditioned bradycardia in the sea lion *Zalophus californianus*

HEART rate is usually reduced when aquatic mammals dive. The degree of this reduction, known as bradycardia, is remarkable[1-3], and immersion in water has been regarded as important in its initiation[3,4]. The heart of the phocid seal beats slower in forced or restrained dives than during trained or voluntary dives[5,6], and bradycardia occurs during respiratory pauses in air as well as in water[7-9]. Central nervous system (CNS) control of bradycardia has been suggested[5,6,8,9]. We have investigated whether bradycardia can be conditioned in the California sea lion *Zalophus californianus* since cardiovascular responses can be conditioned in man and many other animals[10].

Radiotelemetry devices were surgically implanted into two sea lions under the external thin muscle layer just posterior to the right axilla. One sensing electrode was on the transmitter package with a second on a lead extending across the thorax about 20 cm toward the ventral midline. The telemetry devices contained a magnetic switch by which the transmitter could be turned off between experiments. The transmitters were still in place and functional 18 months after the operations. Frequent physical and haematological examinations revealed no damage to the animals.
Fig. 1 Each point represents the time required for the sea lion's heart rate to reach 25 beats min⁻¹ (as gauged by the two intervals between three successive QRS complexes). Of the 90 3–5 minute sessions of breath holding, 71 were plotted. Nineteen apnoeic periods were discarded because the heart rate remained above 25 beats min⁻¹, ECG data was incomplete because of radio interference, gross movement of the animal, or other equipment related technical problems. The regression line was fitted to these points: circle with dot, first period of apnoea in each training session; triangle with dot, shortest latency, that is the period of apnoea during each training session when the shortest latency between onset of apnoea and achievement of the 25 beat min⁻¹ rate was achieved; circle with triangle, first and shortest same, that is, the first period of apnoea in a training session also showed the shortest latency.

After a 2 week recovery period after the operation, one sea lion was conditioned to hold its breath in air (that is, the animal's body was out of the water and dry). The trainer would place his hand near the floor and give the command "down". The sea lion would respond by placing its snout against the trainer's hand and holding its breath until a bridging signal (a police whistle) was sounded. In this way 90 sessions of breath holding of 3–5 min duration were recorded from 20 training sessions during about 2 months. In initial trials bradycardia was slow to develop, and about 90 s were required to reach a basal rate of 25–40 beats min⁻¹ from a mean before breath holding of 120 beats min⁻¹. As Fig. 1 shows, the time required to reach a basal rate of 25 beats min⁻¹ became shorter with successive trials.

The other sea lion, which had no previous training, was conditioned to reduce its heart rate in response to an acoustic command signal. Ordinarily a sea lion's heart beat cycles with respiration[7-9], increasing to 100–140 beats min⁻¹ during breaths and decreasing to about 60–90 beats min⁻¹ between breaths. These normal episodes of bradycardia were reinforced during initial training. When a criterion of three successive beats at the slowed rate was reached, a bridging signal was sounded and a reward of fish was given. At first the sea lion was required to reduce the rate to 80 or 90 beats min⁻¹. This requirement was gradually reduced a few beats at a time until a heart rate of 10 beats min⁻¹ was achieved within 20 s after the bradycardia command was sounded.

The sequence of events was as follows: The sea lion entered a cage. The transmitter was turned on by passing a small magnet by the animal's right axilla. The telemetry signal was received on an f.m. radio, decoded and recorded. The audio output of the radio (a 'beep' for each heartbeat) could be heard by the trainer and the animal. The electrocardiogram (ECG) and command signals were recorded continuously on a Grass polygraph (Model 78). The trainer pushed a button to present the bradycardia command signal. When the heart rate reached the previously determined rate within the prescribed time, the trainer sounded the bridging stimulus, then gave the animal a fish through an opening in its cage. Recordings from one such session are shown in Fig. 2a.

To compare conditioned bradycardia with immersion bradycardia, we decided to repeat Elsner's[5] experiments. The same sea lion was then trained, using another acoustic command signal, to immerse its head in a pail of water. The results were very similar to those of Elsner[5]. Immersion was followed by bradycardia (25–40 beats min⁻¹) within a few seconds (Fig. 2b). Immersion bradycardia, however, was not as pronounced as that achieved in the previous heart rate conditioning trials (Fig. 2).

Bradycardia that resulted from simple apnoea was much slower occurring than that resulting from immersion or conditioning. In the case of the first sea lion, which was required to hold its breath for a relatively long period (3–5 min), bradycardia developed more rapidly with succeeding trials. This suggests at least two possibilities. The animal may have learned that more prompt bradycardia made breath holding easier, but learning could not be demonstrated by analysis of data from this experiment. The second possibility is that the sea lion's bradycardia became more prompt as a result of physiological adjustment with repetition (that is, analogous to physical training of an athlete).

The second sea lion definitely learned some response that caused a rapid and profound reduction in heart rate. Certainly, breath holding was involved, but the extent of bradycardia achieved during our conditioning experiments was considerably greater than that during similar periods of apnoea or water immersion. Our findings suggest that the sea lion is capable of some control of its heart rate. Such control can be conditioned directly or may come about

Fig. 2 ECG of the second sea lion. The three different sound stimuli used to signal the animal were indicated on the recordings. *a*, The animal was in a cage in air and dry. The bridge was used to signal correct performance and to indicate to the animal that a fish reward would soon be given. The bradycardia command was meant to signal the animal to reduce its heart rate. *b*, The immersion command signalled the animal to immerse its head in a pail of water. The bridge again signalled correct response after which the sea lion could lift its head from the water and receive a fish.

through some incidental body adjustment of which we are unaware at present (such as, Val Salva's manoeuvre or contraction of respiratory muscles).

The California sea lion has proved to be a tractable laboratory animal that is readily trained to cooperate in experiments. The degree to which it can alter such autonomic processes as bradycardia and peripheral vasoconstriction[1,2,3] may make it an excellent animal for certain studies involving the CNS control of these responses.

We thank R. L. Seeley for electronic support and B. L. Scronce for advice on training the sea lions. Dr W. F. Flanigan and F. G. Wood made helpful suggestions on the manuscript.

Precocious sexual parasitism in the deep sea ceratioid anglerfish, *Cryptopsaras couesi* Gill

THE eleven families and nearly one hundred species of ceratioid anglerfish are distributed throughout the world's oceans below a depth of 500 m. The Ceratiidae, with two monotypic genera, *Ceratias* Kröyer and *Cryptopsaras* Gill, is one of four ceratioid families whose members exhibit a peculiar and unique mode of reproduction in which dwarfed males become permanently and parasitically attached to the body of a relatively gigantic female. Males of this family have large, forwardly directed eyes, apparently relying entirely on vision for their search and identification of a conspecific female. As in other ceratioid males, they are also equipped with a set of pincher-like denticles at the tips of their jaws for grasping and holding fast to a mate. Attachment is followed by fusion of epidermal tissues, and eventually by a uniting of the circulatory systems, so that the male, whose single function is to produce sperm, becomes dependent on the female for blood-transported nutriment, and the female becomes a kind of self-fertilising hermaphroditic host. Since its discovery 50 years ago, the story of sexual parasitism in ceratioid anglerfish has become a part of everyday scientific knowledge, yet no thoroughly satisfactory analysis of the known facts concerning this remarkable reproductive strategy has been made, in spite of the elegant work of Bertelsen[1]. This report describes sexual parasitism in surprisingly young females of *C. couesi*. Contrary to previous thought, it is now evident that parasitic attachment can take place at an extremely early age immediately following metamorphosis.

It has long been assumed that before acquiring a parasitic male, female ceratioids must mature to an adult stage, that in some forms (especially ceratiids) is of considerable size[2-4]. The smallest known *Ceratias holboelli* with an attached male is 460 mm long[5] (all fish lengths are measured from the snout to the base of the caudal fin). Before this report, the smallest known, sexually parasitised *C. couesi* female was 176 mm long[6]. In recent years, however, two considerably smaller
Fig. 1 *C. couesi* female with parasitically attached male, 15.5 and 9.8 mm long (measured from snout to base of caudal fin), respectively (US National Museum, Washington, DC). ×3.75.

C. couesi females with attached males have been discovered. The larger of these is a 77 mm female with a 15 mm male well fused by upper and lower jaws to her belly just to the right of the mid-line (Institute of Oceanographic Sciences, Surrey, UK). Both members of this pair are fully metamorphosed, having darkly pigmented spinulose skin. The testes are large, occupying well over half the volume of the coelomic cavity. In contrast, the paired ovaries are not well-developed, but similar in size to those of non-parasitised females of a similar length.

The second sexually parasitised female *C. couesi* to be described here (Fig. 1; US National Museum, Washington, DC), is remarkable for her small size. At 15.5 mm she is by far the smallest known ceratioid with an attached male. The 9.8 mm male, fused by both upper and lower jaws to the left side of the female just behind the opercular opening, is the smallest known parasitic male of this species. Metamorphosis,

however, is complete in both sexes. The spinulose skin of the female is darkly pigmented; the ovaries are minute. The skin of the male is spinulose, in contrast to free-living males of this genus[7]. Although the testes are considerably larger than those of free-living *C. couesi* males, its small size, lightly pigmented skin, and well-developed eyes, characteristic of free-living males of this species, indicate the youth of this attached male[8]. Bertelsen[9] argued that *C. couesi* females take at least 6 months to reach a length of 15–20 mm, and that males of this species have the shortest free-living stage of any ceratioid examined, probably lasting in most cases less than 6 months. If it can be assumed that the parasitic relationship between these two has not impaired normal growth rates, then the members of this attached pair are both quite young, perhaps 6 months and certainly less than 12 months old. As tissue fusion between the two is extensive, attachment probably occurred some considerable time before capture when both partners were at an earlier stage of development than indicated by their present size and condition.

Members of the family Ceratiidae are among the most commonly collected ceratioids. *C. couesi* is now represented in collections by well over 200 metamorphosed females and approximately 75 free-living males. In all of this material, only nine examples of sexually parasitised females are known to the author (Table 1). Examination of the size distribution of these nine females with attached males throughout the bulk of the known material of *C. couesi* (Fig. 2), shows a statistically significant progression of increase in incidence of parasitism with increase in size (*P* < 0.001, by χ^2). Only 0.7% of the 143 females 75 mm and smaller are parasitised by a male. Of the 158 females 150 mm or less, only 1.3% are parasitised, whereas 50% of the 14 females greater than 150 mm are parasitised.

It seems that a female *C. couesi* is able to elicit a search response in a conspecific male, as well as provide cues for specific identification by that male, at a surprisingly early age. Clearly, however, such early attachment is rare.

Gonadal development and sexual maturity of both males and females seems to be dependent on their mutual presence in an obligatory, sexual parasitic association. At least four of the nine known attached males of *C. couesi* have well-developed testes, yet no free-living male with large testes has ever been discovered. Similarly, gravid females are known, but none without an attached male (Table 1). Of the nine known parasitised females of *C. couesi*, most have ovaries with eggs in various stages of development (Table 1). The two
Fig. 2 Distribution by length (measured from snout to base of caudal fin) of nine known sexually parasitised females throughout the bulk of known material of *C. couesi*, showing a statistically significant progression of increase in incidence of parasitism with increase in female size (observed values are significantly different from the expected by χ^2, *P* < 0.001). Material is divided into five size classes of 75 mm each. White bars and black bars indicate number (above column) of non-parasitised and parasitised females, respectively. Percentage of parasitised females is indicated for each size class.

smallest examples, however, are sexually immature, yet their attached males have well developed testes. Had these two small pairs survived the nets of biological oceanographers, the male probably would have remained in a state of sexual readiness for some considerable time until the female reached adult size. On the other hand, perhaps the presence of the male would have led to an early maturation of the female. If so, what have so far been called adolescent females are in actuality 'potential' adults only waiting for the parasitic presence of a male to stimulate ovarian development.

That ceratioid anglerfish, alone among vertebrates, have evolved a reproductive strategy of male dwarfism and obligatory sexual parasitism, can be understood when it is realised that population densities of these organisms are low and mobility restricted by a luring mode of energy capture and by an environment that is vast and productively poor. That parasitic attachment can take place at any time during the apparently long life of a ceratioid[10,11], even at a stage immediately following metamorphosis, and thereby making every meeting of a conspecific male and female a potentially sexual affair, makes this solution to the seemingly difficult problem of reproduction in the deep sea, even more remarkable.

Inversion heterozygosity and the origin of XO daughters of *Bpa*/+ female mice

THERE has long been an interest in developing mouse stocks carrying chromosome inversions for mutation testing. This interest stems from the fact that heterozygosity for a paracentric inversion, that is, a structural rearrangement in which a chromosome segment that does not include the centromere is rotated through 180°, results in suppression of recombination in the inversion region. This is caused by the failure of recovery of the products of single crossovers in this region, because dicentric chromatids and acentric fragments are produced that either fail to give functional meiotic products or result in the formation of unbalanced zygotes which are generally eliminated. Recombination between the pair of chromosomes concerned is, therefore, confined to any crossovers in the non-inverted regions and to the rare two-strand double crossovers which may occur within the inversion region if it is a long one. This property of inversion heterozygotes enables the recovery, in the progeny, of the structurally normal homologue largely intact and any recessive mutation located on it can be readily detected if suitable genetically marked stocks are used. In the simplest case, when the mutation is a recessive lethal and the inversion is located in the X chromosome, detection is either by the absence of half the males, or if the inversion itself is marked by a recessive lethal (as in the C1B method devised by Muller for *Drosophila melanogaster*), by the absence of all the males.

Roderick[1] has made a systematic search for autosomal inversions in the mouse but his method does not recover inversions in the X chromosome. An X chromosome inversion, however, besides being simpler to use, would be far more efficient for mutation testing primarily because detection could be achieved in only two generations rather than the three that would be required using an autosomal inversion. We now report the finding of such an inversion among the descendents of a male that had received a fractionated dose to the spermatogonia, of 12 × 50 rad X rays given at weekly intervals. It was found associated with bare patches (*Bpa*), a mutation which proved to be sex-linked and male lethal[2]. The original *Bpa*/+ females produced, among their progeny, considerable numbers of XO daughters all of the rare OXᴾ type[3]. This enhanced capacity to produce XO progeny was subsequently shown to be separable from *Bpa* and was termed *Fxo* (ref. 4). The presence of *Fxo* also suppressed crossing over between *Bpa* and *Ta* or *Blo* and it was suggested that a structural mutation of the X chromosome, perhaps an inversion, might be involved[4].

A long paracentric inversion of the X chromosome has now been demonstrated cytologically in *Bpa Fxo*/++ animals and shown to be absent from *Bpa*+/++ animals; therefore the symbol *Fxo* has been withdrawn and replaced by In(X)1H (ref. 5) in accordance with the standardised nomenclature for the mouse[6].

The inversion was first identified cytologically by the presence of characteristic bivalents at diakinesis in oocytes from *Bpa* In(X)1H/++ heterozygotes and was confirmed in Giemsa-banded preparations[7] made from bone marrow. Preliminary observations suggest that it extends from a proximal break point lying just within the dark centric band (A1 of Nesbitt and Franke[8]) to a point distal to band E and that it represents about 85% of the physical X chromosome (Fig. 1).

An average of 30 chiasmata per oocyte has been observed
Fig. 1 X chromosomes from three cells heterozygous for the inversion. In(X)1H chromosome is on the right of each pair and inverted in relation to its normal homologue. Lines join presumptively homologous bands. Direct bone marrow preparations stained by trypsin–Giemsa method.

at diakinesis in normal, structurally homozygous mice (C. E. Ford and E. P. E., unpublished). If these are partitioned between bivalents in proportion to the lengths of the chromosomes at somatic mitosis[19], the mean number in the X bivalent would be 1.81. Distributing these in proportion to segment length, the mean number of chiasmata within the inversion region would be approximately 1.54, which would correspond to a genetic length of 77 centiMorgans (cM). This is greater than the total length of the current X chromosome map (75 cM; Fig. 2) and would imply that most, perhaps all, the mapped loci lie within the inversion.
Fig. 2 Map of the X chromosome of the mouse showing the effect on recombination of In(X)1H. *a*, Standard map; *b*, from *Bpa* non-In(X)1H females; *c*, from *Bpa* In(X)1H females. Units represent percentage crossover.

A minimum estimate of the length of the inversion can be obtained independently from the genetic evidence. Data on the recombination between *Bpa* and the other three loci in the absence of In(X)1H (Table 1) indicate that *Bpa* lies between *spf* and *Ta*. Strong crossover suppression had been shown to occur between *Bpa* and *Ta*, and between *Bpa* and *Blo* (ref. 4); it has now also been demonstrated between *Bpa* and *spf* as well (Table 1 and Fig. 2), that is, crossover suppression occurs on both sides of *Bpa*. Also recombination between *Bpa* and either of the markers *Ta* or *spf*, leaves In(X)1H on the unmarked chromosome (Table 1). Together, this evidence implies that *Bpa* lies within the inversion, and therefore to separate *Bpa* from In(X)1H would require a double crossover with one

Table 1 Segregation from: (1) $Bpa+/+Ta \times Blo$ Y*; (2) $Bpa+/+Blo \times Ta$ Y*; and (3) $Bpa+/+spf \times spf$ Y in the presence and absence of In(X)1H

‖All three recombinants from cross (1) and one from cross (3) have been tested and shown still to carry In(X)1H.

exchange on each side of the Bpa locus. The frequency of separation has been estimated by testing Bpa daughters of Bpa In(X)1H mothers not carrying any other sex-linked gene. Seven of 87 such daughters proved to have lost the inversion ($8.05 \pm 2.92\%$).

If Blo does lie outside the inversion, recombinants between Bpa and Blo in the presence of the inversion would include all Bpa-In(X)1H double crossovers plus any crossovers between the distal break point of the inversion and the locus of Blo. But the estimated recombination between Bpa and Blo (2.45%) is less than between Bpa and the inversion (8.05%); Blo therefore probably lies within the inversion. The same argument can be applied to Bpa and spf (3.80%), and spf more likely than not lies within the inversion. The genetic data are, therefore, consistent with an inversion greater than 48 cM long.

At the stage when the tentative hypothesis for an inversion was first put forward the non-Bpa In(X)1H chromosome had not been obtained[4]. Subsequently both +In(X)1H/++ and +In(X)1H/Y animals have been produced. The females as expected, give a similar percentage of XO progeny to their Bpa In(X)1H/++ counterparts, but the males do not give XO offspring.

A greatly increased frequency of XO daughters would be anticipated among the progeny of females heterozygous for an X chromosome inversion. The dicentric chromatid resulting from a single chiasma within the inversion region would be expected to lead to a chromatid bridge at anaphase I. Whether this was left on the spindle, broken, or incorporated intact into the secondary oocyte (or polar body) nucleus, its eventual elimination would be inevitable, and although the dicentric itself has not yet been recognised a first rough assessment suggests that the frequency of bivalents with a single chiasma in the inverted segment is about 0.4. Elimination could occur either at meiosis or subsequent to fertilisation. In either case an equal frequency of XO and OY individuals would be expected. Crossing over within the inversion is necessarily excluded in In(X)1H/Y males and no XO offspring would be expected.

On the basis of all this evidence, therefore, it seems certain that we are dealing with a very long sex-linked inversion. The occurrence of double crossing over would reduce its efficiency for mutation testing compared with the Muller-5 stock of Drosophila although this may be more than compensated for by the accurate estimates of probability of mutation that would be possible. In any case a technique based on the In(X)1H inversion, already marked by the male-lethal mutation Bpa, would be far more efficient than the methods at present in use for estimating the frequency of sex-linked lethals in mice[10].

Limited potential of circulating haemopoietic stem cells

IT has long been known that animals irradiated with a lethal dose may recover if the spleen is shielded during exposure[1], or if normal bone marrow or spleen cells are subsequently injected intravenously[2]. Recovery has been shown to be the result of repopulation of the damaged haemopoietic tissues by stem cells from the donor[3]. It was later found that cells with at least some of the characteristics of stem cells were present in the blood of normal mice[4–6]. These characteristics included the formation of spleen colonies and the ability to promote recovery from lethal irradiation, at least in the short term. Some studies[7] have suggested that circulating stem cells are equivalent to those in bone marrow, while others[8] have indicated certain differences.

In spite of evidence that at least some stem cells are mobile, other data imply that the actual interchange of stem cells between different bone marrow sites may normally be limited or absent[9–14]. Calculations[14] show that, at most, only a small proportion of circulating stem cells enter the bone marrow and find haemopoietic clones. A possible explanation for this is that circulating stem cells have a limited capacity for self renewal. This hypothesis has been tested in two experimental systems.

The first approach was to investigate the relative regeneration of spleen colony-forming units (CFU)—stem cells which home to the spleen—in spleens carrying colonies derived from bone marrow or blood. The experimental scheme and results of four experiments are shown in Table 1. In addition, radioiodinated 5-iodo-2-deoxyuridine (IUdR) was injected into mice in two of the experiments to measure DNA synthesis (Table 2).

*Normal BM or blood cells were injected intravenously to lethally-irradiated (900 rad) primary recipients. Eight days later the recipients were killed. Their spleens were divided into two groups; half were fixed for counting of spleen colonies; the remainder were pooled and cell suspensions were prepared in Hanks' solution for intravenous injection to secondary 900 rad-irradiated recipients. These were killed 8 d later, after injection of ^{125}I-IUdR (see Table 2), and their spleen colonies counted. The RI (column 7) was calculated as column 6/column 5 (that is, CFU per colony equivalent injected). Irradiated, non-injected control mice never developed spleen colonies.
†Numbers of mice in parentheses.
‡Heparinised blood was injected whole (experiment 1), or after sedimentation of erythrocytes with Plasmagel (Lab. R. Bellon, Neuilly, France).

The stem cell population derived from blood, assayed as CFU, renewed its numbers far less effectively within 8 d than that derived from bone marrow. The few colonies that did develop in the secondary recipients of blood-derived spleen cells were mostly small, and barely detectable without a hand lens; recipients of marrow-derived spleen cells, on the other hand, developed colonies of normal size. DNA synthesis (and thus cell proliferation) was also relatively slight, although the difference between the groups was less than would have been predicted from the colony counts. Some of the cell proliferation may be attributable to the descendants of injected splenic lymphocytes (originally derived from the primary blood inoculum); terminally differentiating microcolonies of haemopoietic cells may also contribute. The circulating stem cells of mice rendered anaemic with phenylhydrazine have also been shown to have relatively poor powers of self renewal[15].

In experiment 4, the doubling time of CFU between day 8 and day 10 was the same in marrow-derived and blood-derived colonies (20–21 h), which agrees with the data of Gidali *et al.*[8].

The overall regeneration of haemopoietic populations derived from blood and bone marrow stem cells was compared directly by means of chromosome markers. Groups of mice were injected with a mixture of syngeneic bone marrow and blood cells distinguishable by the possession of one or two T6 chromosomes and killed at intervals for cytological examination of mitotic cells[16]. Although the presence of the markers does not affect the proliferative fitness of a population[17], two experimental groups were set up with reciprocally marked donor cells as a precaution. The cell doses were weighted 100-fold in favour of blood, so as to obtain roughly equal numbers of stem cells initially. The suspensions were tested individually for their CFU content. During the second week after injection, the contribution of blood-derived cells to the mitotic populations in the haemopoietic system dropped sharply. By day 23 they constituted less than 5% of the total donor-derived population (Fig. 1).

These experimental results imply that blood and bone marrow stem cells differ markedly in their self renewal, and in the size of descendant populations which they produce in identical conditions. A possible interpretation of the spleen colony data, taken in isolation, would be that blood CFU

Table 2 Splenic uptake of IUdR in lethally-irradiated recipients of cells from colony-containing spleens*

Exp.	Cell injected to primary recipients	Splenic IUdR uptake (geometric mean) in secondary recipients	
		Total specific uptake/spleen†	Specific uptake per colony- equivalent injected (ratio BM: blood)

			(4.1)

*Details of mice are given in Table 1. Three hours before death mice were injected intraperitoneally with 5×10^{-8} mol fluorodeoxyuridine followed after 1 h by 1 μCi ^{125}I-IUdR (specific activity, 5 mCi mg^{-1}: Radiochemical Centre, Amersham) as previously described[30]. After washing out of non-DNA-associated radioactivity, spleens were counted in a Packard crystal scintillation counter. ^{125}I-uptake was expressed as a proportion of the injected activity; counts $\times 10^6$ per injected counts.
†Numbers of mice in parentheses. 'Specific' uptake was that attributable to the donor cell population, after subtraction of the mean uptake in irradiated, non-injected controls.

(and/or their CFU descendants) have different homing or migratory properties from marrow CFU, without necessarily differing in their rate of growth. The results of the competition experiment (Fig. 1) argue against such an interpretation. Taken together, the data strongly suggest that although blood CFU are able to engender differentiating clones which grow within 1–2 weeks to perhaps a few million cells, they have, on average, little ability to increase their numbers and thus produce larger and more persistent clones. The presence of a minority of relatively efficient stem cells in the blood is suggested by the similar growth rate of blood-derived and marrow-derived CFU between 8 and 10 d following transplantation.

Calculations based on a stochastic model of haemopoiesis[18] have suggested that in conditions of haemopoietic regeneration in the spleen, the average probability of two new CFU resulting from the division of an existing CFU is 0.62–0.64 (refs 19, 20); in these conditions the CFU pool expands. If this probability is similar for bone marrow stem cells under steady-state conditions, a certain surplus of CFU will be produced continually in the bone marrow. Such a surplus may either be eliminated in situ, or discharged into the bloodstream. These processes may be random, or they may act selectively on, for example, stem cells with a relatively long mitotic history. The present results show that stem cells in blood are not a random sample of those in bone marrow, but are a selected population of generally low proliferative potential. Serial subculture of diploid cells in vitro[21,22] and serial transplantation of tissues[23–25] and haemopoietic cells in vivo[3,20,26–29] cannot be continued indefinitely; after a certain number of divisions the cells cease to multiply. By analogy, it is reasonable to speculate that the CFU normally found in blood are victims of clonal senescence, and have been expelled as waste products from the bone marrow.

Evidence for the low proliferative potential of circulating stem cells is derived almost entirely from work on bachelor male mice of the inbred strain CBA and its congenic line CBA-T6, bred and maintained in conventional conditions. It remains to be seen whether this potential is equally low in other animals and whether it can be enhanced by experimental means.

Independent regulation of cellular properties in thermosensitive transformation mutants of mouse fibroblasts

CHEMICAL[1] or viral[2] transformation of fibroblasts in tissue culture results in cells with altered properties (for review see ref. 2). These properties can be broadly subdivided into those associated with changes in the plasma membrane[3] and those associated with intracellular regulatory changes[2]. The former changes include the ability to grow in soft agar[4], the loss of an iodinatable surface glycoprotein[5,6] and an increase in total cell-membrane-associated proteolytic activity[7] on cell transformation. The chief manifestation of intracellular changes is the failure of transformed fibroblasts to cease growing at a specific point (G_1 or G_0) in the cell cycle[8] and thus to express the typical increases in protein synthesis, ribosomal RNA synthesis and DNA synthesis upon growth reinitiation[9]. We have now investigated some of these properties in cell mutants of BALB/c-3T3 which show temperature-dependent changes in many properties characteristic of the transformed state in tissue culture. These mutant cells behave as normal mouse fibroblasts in the regulation of their internal cellular machinery at permissive or non-permissive temperatures but show temperature sensitive changes in those properties we have measured which are considered to be associated with membranes.

Both virus and cell mutants which give rise to temperature sensitive (ts) lesions in many properties characteristic of transformed fibroblasts have been reported[10–12]. Eckhart has

Table 1 Summary of intracellular changes after addition of serum

Cell type	Temperature (°C)	Ratio: newly growing cultures/resting cultures			
		Protein synthesis	rRNA synthesis	DNA synthesis	Cell no.
BALB/c–3T3	32	2.0	2.0	95	1.9
	39	1.8	2.0	86	1.8
ts Cl.1	32	2.0	2.3	35	1.7
	39	2.4	2.0	68	1.9
ts Cl.10	32	2.6	2.3	39	1.7
	39	2.5	1.8	90	2.0
ts Cl.X	32	2.0	1.9	30	1.8
	39	2.0	2.0	55	1.8
Py3T3–Swiss	32	1.1	1.0	1.3	1.1
	39	1.1	1.1	1.4	1.0
SV3T3–BALB/c	32	1.1	1.1	1.0	1.0
	39	1.2	1.0	1.1	1.1

Non-transformed (BALB/c-3T3) mutant (ts Cl.1, ts Cl.10, ts Cl.X) and virally transformed –3T3 (BALB/c–SV3T3, Swiss Py3T3) cells were grown as described previously[13] in Dulbecco's modified Eagles medium (DEM) containing 10% foetal calf serum at either 32 or 39 °C until they formed a confluent monolayer. The medium was removed and replaced with DEM and 1% foetal calf serum for 3 d. Then the medium in half the cultures was replaced with fresh DEM and 20% serum. Protein synthesis was measured by exposing the cultures to 0.2 μCi ml⁻¹ of (^{14}C–U) amino acid mixture (specific activity 57 mCi per matom) from 4 to 6 h at 39 °C or from 8 to 12h at 32 °C; RNA synthesis with 1 μCi ml⁻¹ ^{3}H-uridine at 5×10^{-6} M from 10 until 16 h at 39 °C or from 20 until 32 h at 32 °C. The fraction of cells with ^{3}H-thymidine radioactively labelled nuclei[9] was recorded for cells exposed to ^{3}H-thymidine throughout the DNA synthetic period (from 10 until 30h at 39 °C and from 20 until 60 h at 32 °C), and the cell numbers were recorded after 48 h at 39 °C and 96 h at 32 °C respectively. The radioactivity incorporated into protein was expressed per mg of cell protein. The radioactivity of ^{3}H cytoplasmic ribosomal RNA (rRNA) synthesised in the time period per mg of cell protein was corrected for the differential incorporation rates into the trichloroacetic acid-soluble RNA precursor pool as previously described[9,22]. Previous results for changes in nontransformed fibroblasts[3] cytoplasmic rRNA synthesis by this method agreed with those obtained by other authors from direct measurements of intracellular specific activities of the RNA precursors[22]. Incorporation of ^{14}C amino acids into protein or ^{3}H-uridine into RNA (18S and 28S) increased linearly with the time of exposure to the radioactive macromolecular precursor. Results are expressed as a ratio of the synthesis or cell number after quiescent cultures were induced to grow with fresh serum to those values before the culture medium was changed. Errors in the ratios are approximately 10–15% for protein, RNA synthesis, and cell numbers, and 20–25% for the radioactively labelled nuclei.

isolated different clones of BALB/c–3T3 cells which grow in agar at 32 °C (W.E., unpublished). Cells from these clones show transformed morphology, ability to grow in agar, higher growth rates and higher saturation densities at 32 °C than at 39 °C, although at low concentrations of serum in the tissue culture medium they exhibit density-dependent inhibition of growth at both 32 °C and 39 °C similar to non-transformed cells but unlike the virally transformed cell lines Py3T3 and SV3T3[13]. In this paper three independent ts mutant clones of BALB/c–3T3 cells (ts Cl.1, ts Cl.10 and ts Cl.X) were tested for temperature-dependent changes in various cell properties. Cells were grown in 10% serum and then arrested in their growth by a reduction in the serum concentration to 1%. On addition of fresh medium and 20% serum to the quiescent mutant cells at either 32 or 39 °C they increased the overall rate of protein synthesis, cytoplasmic RNA synthesis (28S and 18S RNA), initiated DNA synthesis and divided (Table 1) just as their parent cell[9]. The time scale for the increase in macromolecular synthesis and cell division was twice as slow at 32 °C than at 39 °C (Table 1). In particular for both the mutant and BALB/c–3T3 cells at 39 °C DNA synthesis was

initiated at 8–10 h, reached a maximum at 18–20 h and was followed by virtually complete cell division by 40 h, whereas for parent and mutant cells at 32 °C DNA synthesis was initiated at 16–18 h, reached a maximum at 34–36 h and was followed by nearly complete cell division by 80 h. Thus the mutant cells were uniquely arrested in growth in the same position of the cell cycle as their parent BALB/c–3T3 cell (G_1 or G_0) at both temperatures and had not ceased growing at random[14]. The fully transformed BALB/c–3T3 cells SV3T3 and Swiss Py3T3 did not show density-dependent inhibition of growth at low serum concentrations, and thus did not appreciably increase rates of macromolecular synthesis and cell division on readdition of 20% serum (Table 1).

Recently the loss of a large, external, transformation-sensitive (LETS) protein has been described after viral or chemical transformation of fibroblasts[5,6]. This has been demonstrated using lactoperoxidase-catalysed iodination. The mutant clones of BALB/c–3T3 cells were arrested in their growth at confluency (Table 1), then radioactively labelled with ^{125}I *in situ*, and the iodination patterns analysed on SDS-polyacrylamide gels (Fig. 1). The radioactive LETS

a b c d e f g h i j
Fig. 1 Autoradiograph of ^{125}I-labelled cells after SDS-polyacrylamide gel electrophoresis. BALB/c–SV3T3 cells grown at: *a*, 32 °C and *b*, 39 °C; BALB/c–3T3 at *c*, 32 °C and *d*, 39 °C; ts Cl.1 at *e*, 32 °C and *f*, 39 °C; ts Cl.10 at *g*, 32 °C and *h*, 39 °C; ts Cl.X at *i*, 32 °C and *j*, 39 °C. Confluent cultures of cells were iodinated as previously described[6] directly on the dish. Before iodination, the cells were washed twice at room temperature with phosphate-buffered saline (PBS), *p*H 7.2 and to each 5-cm dish was added 0.5 ml of PBS containing D-glucose (0.9 mg ml⁻¹) and carrier-free Na^{125}I (400 μCi ml⁻¹). Then 10 μl of an enzyme mixture containing lactoperoxidase (1 mg ml⁻¹) and glucose oxidase (0.1 U ml⁻¹) was added for 10 min at room temperature. The reaction was stopped by the addition of 5 ml of 0.17 M NaI in 0.01 M sodium phosphate buffer, *p*H 7.2. The cell monolayers were then washed twice with PBS, the cells were scraped off the dish with a rubber policeman and rewashed with 0.1 M Tris-HCl (*p*H 6.8) containing 15% glycerol. Samples of 10⁵ c.p.m. were collected by centrifugation, adjusted to 2% sodium dodecyl sulphate and 0.1 M dithiothreitol, and boiled for 2 min. Polyacrylamide gel electrophoresis[23] was performed in a slab gel at an acrylamide monomer concentration of 7.5%. After electrophoresis, the slab gel was dried in a vacuum and autoradiographed for 4 d using Kodak X-ray film RP/R54 to locate the radioactively labelled components.

glycoprotein of nominal molecular weight 250,000 was observed in the parent cells and the ts cells at 39 °C but had virtually disappeared in the ts cells at 32 °C and the BALB/c–SV3T3 transformed fibroblasts. Several other radioactively-labelled components disappeared when the mutant cells were grown at 32 °C instead of at 39 °C, although whether these reflected changes in plasma membrane composition or differential adsorption of serum components to the cells at the two temperatures is unknown. The same pattern was observed if the mutant cells were grown in 10% serum and radioactively labelled when confluent (not shown).

The cell factor that is involved in tumour-associated fibrinolysis occurs in the postnuclear particulate fraction of Rous sarcoma virus transformed chick embryo fibroblasts, although its exact membranous location has not yet been determined[7]. This arginine-specific protease converts serum plasminogen to its enzymatically active form plasmin. The plasmin in turn can be detected by its capacity to hydrolyse ^{125}I-fibrin[15] or the milk protein casein in an agarose overlay assay[16]. Cells were grown as before (Table 1) and assayed for the production of the cell factor by the degree of hydrolysis of casein with either 1% monkey serum, 0.5%

permanently at 32 °C in all the tests used, and *vice versa*. After more than 20 passages in cell culture ts Cl.1 cells started growing in agarose at 39 °C and simultaneously the iodinated LETS glycoprotein was not detectable and the proteolytic activity increased from 0 to +2.

Previous reports have indicated that many of the properties characteristic of the transformed state change in a coordinate manner on viral transformation of fibroblasts. But the isolation of stable SV40-transformed 3T3 cells with partially transformed characteristics[17-19] and SV40-transformed rat embryo cells which continuously express the viral T antigen but coordinately vary in anchorage dependence and plasmin activator production[20], have demonstrated that SV40-induced transformation of fibroblasts can lead to a variety of stable changes. The dependence of BALB/c–3T3 fibroblasts on anchorage for growth may be directly responsible for their failure to induce tumours in animals[21]. We have now shown in the same temperature-sensitive mutant cell that those properties considered to be associated with the surface membrane, the ability to grow in agarose, the disappearance of the iodinatable glycoprotein, the loss of the growth-promoting ability of the fibroblast growth factor[13] and the increase in total cell membrane proteolytic

Table 2 Proteolytic activity and growth in agarose

Cell type	Temperature (°C)	Degree of casein hydrolysis (scale 0 to 4)			Colony formation (%)
		Monkey serum	Dog serum	Plasminogen

	39	ND	3	3	40
SV3T3–BALB/c	32	4	4	4	ND
	39	4	4	4	ND

For the measurement of fibrinolytic activity the conversion of serum plasminogen to plasmin by the cell activator[7] was measured by the plasmin-induced hydrolysis of casein[16]. Cells grown at their respective temperatures were plated at 10[5] (Monkey serum) or 2 × 10[5] (dog serum and plasminogen) per 3.5 cm Petri dish in DEM and 10% foetal calf serum. After 3 h the medium was removed, cell monolayers were washed twice with DEM and then 1 ml of a suspension of 0.6% agarose, 2% autoclaved powdered milk (Marvel) mixed with one of 1% African green monkey serum (Flow Laboratories) or 0.5% dog serum (Gibco) or 30 μg ml^{-1} of plasminogen purified from foetal bovine serum (gift of Dr R. Hynes) in DEM was added and allowed to solidify at room temperature. Finally, 1.5 ml of 0.6% agarose in DEM was added, allowed to solidify and the dishes were then incubated at 32 or 39 °C until the casein in the dishes containing SV3T3 cells had completely lysed (approximately 40–50 h at 39 °C and 80–120 h at 32 °C depending on the serum used). The remaining plates were scored on a scale of 0 to +4 (complete hydrolysis) according to the proportion of casein removed. Similar results were obtained with 0.25%, 1% and 2% dog serum, but with 10% dog serum there was virtually no differences for the ts cells at 32 °C or 39 °C. Petri dishes containing no transformed cells but with serum or plasminogen, or containing transformed cells but no serum or plasminogen gave no detectable casein hydrolysis, while 0.005% trypsin (w/v) completely hydrolysed the casein within 48 h at either 32 °C or 39 °C. Fibrinolytic assays[15] using the same cells and sera failed to yield definite differences in the rate of proteolytic hydrolysis of ^{125}I-labelled fibrin (not shown). The ability of different cells to grow in agarose was determined by plating 10[4] or 10[5] cells in liquid medium containing 10% foetal calf serum in 5 cm Petri dishes. Cells were overlayered with a suspension of 0.33% agarose and 10% foetal calf serum in DEM, incubated at 32 or 39 °C, and the colonies counted after 2, 3 and 4 weeks. The percentage (%) of cells which grow in agarose is shown. The figures represent the average of 3 separate experiments (8 Petri dishes per experiment) and 2 microscopic fields of 200 cells were counted per Petri dish. The ts cells formed appreciably smaller colonies at 32 °C than the Py3T3 cells. ND, not determined.

dog serum, or purified bovine plasminogen (Table 2). Calf serum contains an inhibitor of the plasmin assay[15] and thus was not used. The extent of removal of the casein was estimated on a scale of 0 to +4 (complete removal). Thus BALB/c–3T3 and the ts cells at 39 °C showed little or no cell factor activity whereas the ts cells at 32 °C, Swiss Py3T3 and BALB/c–SV3T3 showed considerable activity. Results in Table 2 also confirm that the ts Cl.1 and Cl.10 cells formed 30–50 times more colonies in agarose at 32 °C than at 39 °C, although the differences for ts Cl.X were smaller. Similarly the ts cells show decreased plating efficiencies in agar and in liquid medium at 39 °C than at 32 °C. (W.E. unpublished). In controls (not shown) ts Cl.1 cells grown at 39 °C were grown for several generations at 32 °C and these cells behaved identically to the ts Cl.1 cells grown

activity are coordinately changed with the temperature at which the cells are grown. These mutant cells, however, behave as normal fibroblasts at either temperature with respect to the regulation of their intracellular macromolecular synthesising machinery. Unfortunately it is not possible to test the ability of ts mutant cells to induce tumours *in vivo* at 32 °C and 39 °C.

The coordinate changes observed on transformation may not be reflected in every type of cell. Several non-transformed cells containing LETS protein also show significant levels of fibrinolytic activity whereas some transformed cell lines contain LETS protein but have reduced levels of fibrinolytic activity (E.P., R. O. Hynes, V. Hemmings and L. M. Franks, unpublished). Results with our mutant cells, however, suggest that at least two independent

cell functions control the transition from normal to fully transformed fibroblasts and that in these mutant cells the ability to regulate changes in some cell surface properties is uncoupled from major changes in intracellular events.

A "permissive" effect of dexamethasone on the glucagon induction of amino acid transport in cultured hepatocytes

The adrenal glucocorticoids have been shown to be involved in the regulation of cyclic AMP activated metabolic processes such as lipolysis[1], glycogenolysis[2] and gluconeogenesis[3]. The role of the glucocorticoids in the regulation of these processes has been termed "permissive"[4] since it enables the maintenance of the normal responsiveness of cells to hormones which act through cyclic AMP. Glucagon is known to activate the gluconeogenic pathway of mammalian liver at several sites[5] including amino acid transport[6]. We have studied the hormonal regulation of amino acid transport in rat liver parenchymal cells maintained in culture and report here that the synthetic glucocorticoid, dexamethasone, has a "permissive" effect on the glucagon induction of amino acid transport in hepatocytes.

Parenchymal cells from adult rat liver were isolated by a

collagenase perfusion technique and were maintained in monolayer culture in serum-free medium on collagen coated plates as described previously[7-9]. These cells maintain many of the biochemical characteristics of adult rat liver cells for about five days in culture[7-9]. Amino acid transport was measured by studying the uptake of the nonmetabolisable amino acid α-aminoisobutyric acid (AIB).

The data presented in Table 1 established that dexamethasone, when added alone to cultures of adult rat liver parenchymal cells, has no effect on AIB transport. Experiments conducted with higher or lower concentrations of hormone and with longer or shorter times of treatment failed to demonstrate any effect of dexamethasone on amino acid transport. The addition of glucagon to the cultures resulted in a twofold increase in AIB transport. The simultaneous addition of dexamethasone and glucagon, however, produced a fourfold increase in transport. The addition of dibutyryl cyclic AMP to the cells mimicked the effect of glucagon with respect to AIB transport. The simultaneous addition of dexamethasone and dibutyryl cyclic AMP resulted in a further increase in AIB transport relative to those cells treated with dibutyryl cyclic AMP alone.

Table 1 The effect of glucagon, dibutyryl cyclic AMP, and dexamethasone alone and in combination on α-aminoisobutyrate transport

Hormone	AIB transport*
None	0.71 ± 0.02
Dexamethasone	0.70 ± 0.03
Glucagon	1.33 ± 0.06
Dexamethasone and glucagon	2.77 ± 0.11
Dibutyryl cyclic AMP	1.65 ± 0.06
Dexamethasone and dibutyryl cyclic AMP	3.43 ± 0.10

* nmol per mg cell protein per 4 min.
Adult rat liver parenchymal cells, which had been maintained in culture for 8 h, were treated with the indicated hormones for 12 h and then the uptake of 1 mM 2-^{14}C-AIB in 4 min was determined. Uptake of AIB was linear for at least 8 min. The measurement of AIB uptake was conducted in a manner similar to that for the measurement of sugar uptake in cultured cells[10]. Briefly, the procedure consisted of rinsing the cells, which were attached to 60-mm diameter dishes, with 10–15 ml of Hanks'–Hepes medium (at 37 °C and at 8 mM with respect to glucose) and 1.5 ml of this medium containing 1mM 2-^{14}C-AIB was added for 4 min at 37 °C. Incubation was terminated by aspiration of the medium and the cells were rinsed with 15–20 ml of cold phosphate buffered saline. The cells were digested in 0.2 N NaOH and samples were taken for scintillation counting and protein assay[11]. The concentrations of the hormones were as follows; dexamethasone, 10^{-6} M; glucagon, 10^{-7} M; dibutyryl cyclic AMP, 10^{-4} M. This concentration of glucagon gave the maximum induction of transport. Each value represents the mean ± s.e. of 6 plates from 3 separate experiments.

Amino acids are major substrates for gluconeogenesis in mammalian liver[5]. The alanine cycle functions to provide carbon substrate to the liver for gluconeogenesis[12,13]. The glucocorticoids have already been implicated in maintaining the supply of amino acids to the liver since these hormones tend to increase the release of amino acids from extrahepatic tissues[14-16]. The data presented in this report now establish that the glucocorticoids also play an important role in the uptake of amino acids by liver since they are required for the full induction of amino acid transport by glucagon. We believe that this is the first observation of a "permissive" effect of the glucocorticoids on the hormonal induction of a transport system.

The site of action of the "permissive" effect of the glucocorticoids is not known although RNA and protein synthesis may be required[17]. Exton *et al.*[3], have established that cyclic AMP accumulation in perfused rat liver from adrenalectomised animals after glucagon addition was normal but either hydrocortisone or dexamethasone has to be administered to observe the normal glucagon activation of gluconeogenesis. Other work[2] has also suggested that the site of the "permissive" effect is at a point beyond

cyclic AMP formation. Our data are in accord with these results since dexamethasone also had a permissive effect on the dibutyryl cyclic AMP induction of amino acid transport.

Our observation of the lack of any effect of dexamethasone alone on amino acid transport in hepatocytes in culture was rather unexpected since previous reports based on the administration of the glucocorticoids *in vivo* had suggested that these hormones alone can stimulate amino acid transport in hepatocytes[18,19]. The study of hormonal regulation of metabolic processes *in vivo* is, however, always complicated by the effects of the many endogenous hormones. Thus, the use of rat liver parenchymal cells in culture for the study of hormonal regulation of metabolic processes circumvents this problem since these cells can be maintained in a completely defined serum-free medium and still maintain many of the biochemical characteristics of adult rat liver.

Interference with normal phagosome–lysosome fusion in macrophages, using ingested yeast cells and suramin

FOREIGN bodies, including microorganisms, ingested by cultured mouse peritoneal macrophages become enclosed within phagosomes. Usually lysosome granules promptly assemble close to the phagosomes and fuse with their membranes, exposing the ingested objects to digestive enzymes[1–3]. Much of the kinetics of phagosome–lysosome fusion and degranulation in leukocytes was described by Robineaux, Hirsch, Cohn and their co-workers[4–7], but the mechanisms and factors controlling them are only now beginning to emerge[8,9].

Some natural exceptions to the usual fusion pattern in macrophages have been observed, notably the non-fusion response to virulent *Myobacterium tuberculosis*[10] and living *Toxoplasma gondii*[11]. These non-fusion patterns can be reversed by attaching antibody to the organisms before their ingestion[12–14]; extensive phagolysosome formation then occurs. Such deviations and manipulations of phagosome–

lysosome fusion behaviour may help to elucidate its importance in the response of macrophages to intracellular microorganisms. The examples cited have been concerned with the parasite within its phagosome, but we now report successful inhibition of the normal fusion mechanism by a "lysosomotropic" drug (suramin), using a simple rapid method for observing fusion patterns in living cultured macrophages with the light microscope. Lysosomes were prelabelled with acridine orange[15,16] and the phagocytes permitted to ingest live baker's yeast cells; intracellular changes were monitored in the living monolayers by dark-field fluorescence microscopy.
Fig. 1 Living macrophages with acridine-stained lysosomes (L) after incubation with live yeasts for 45 min. Surrounding many yeast cells are brightly fluorescent intraphagosomal "rims" (R), indicative of phagosome–lysosome fusion. Normal pattern of macrophage response.

Established cover slip monolayers of unelicited mouse peritoneal macrophages in Chang medium in Leighton tubes[10,14,17] were given a change of medium, and 2–6 d later were washed with balanced salt solution (BSS) and exposed at 37 °C in BSS to purified acridine orange, 5 μg ml^{-1}, for 10 min. The cells were washed and infected in BSS plus 2.5% human cord serum with a suspension of fresh commercial compressed baker's yeast (*Saccharomyces cerevisiae*) (about 5×10^6 yeast cells per ml; ratio to macrophages about 20 : 1). After 15 min to 6 h at 37 °C (the exposure to the yeast cells usually maintained throughout), cover slips were removed and mounted in BSS, and were examined with blue–violet light[15,16].

Lysosomes fused with yeast-containing phagosomes in characteristic stages during 1–2 h after the start of ingestion. The orange-fluorescing granules assembled around the unstained yeasts. Next, these periphagosomal "satellite" lysosomes disappeared and vivid orange confluent "rims" of fluorescence appeared around the individual yeasts, indicating a discharge of lysosomal contents into the phagosomes (see Fig. 1). Gradually the intraphagosomal dye permeated into the yeast cells, colouring the whole organisms green and then red; some hours later dark holes were sometimes seen, suggesting dissolution of yeast cells by digestive enzymes. These stages overlapped. Both satellite lysosomes and rims were plentiful at 15 min, but rims predominated at 45–50 min; coloured yeast cells increased and became

frequent after about 2 h, with gradual disappearance of rims. Heat-killed yeast cells were unsuitable for observing the fusion process as they took up the dye too rapidly for rims and satellites to be detected.

The monolayers were exposed to various substances that may inhibit the fusion process, before (or after) labelling of the lysosomes; yeast cells were then introduced. We examined some reputed stabilisers of lysosomes (dexamethasone sodium phosphate; chloroquine diphosphate; chlorpromazine hydrochloride); another anti-inflammatory agent (aspirin); an inhibitor of degranulation (colchicine) and also morphine hydrochloride, cyclophosphamide and cycloheximide. None inhibited noticeably the phagosome–lysosome fusion process in our test system.

Suramin (which enhances tuberculous infection in mouse macrophages)[17,18] was then tested. It was incorporated in fresh culture medium for 6 d; the cell layers were washed, stained with acridine orange, and infected with yeast cells as before. Uptake was normal, but 45–50 min after the start of ingestion lysosome satellites were predominant, rims and
Fig. 2 Conditions as Fig. 1 but macrophages pretreated with suramin (200 μg ml^{-1} for 6 d). Lysosomes (L) have assembled as 'satellites' (SL) around many of the ingested yeast cells (Y); fluorescent rims are absent. Non-fusion pattern of response.

coloration of the yeasts being inconspicuous (Fig. 2); concurrent controls at the same time showed mostly rims and some green or red yeast cells (Fig. 1). These appearances were interpreted as almost complete short term suppression of the normal phagosome–lysosome fusion response. They were evident after pretreatment at 200 μg ml^{-1} (maximum tolerated) to 50 μg ml^{-1}, with some inhibition down to 5 μg ml^{-1}. The effect was maintained for at least 5 h after 200 and 100 μg ml^{-1}; however, after 50 μg ml^{-1} a few rims and coloured yeast cells appeared towards the end of this period. The drug at 200 μg ml^{-1} only partly suppressed the fusion response to heat-killed yeast cells. The suppression of fusion by suramin was confirmed by electron microscopy, prelabelling secondary lysosomes with ferritin.

The macrophage monolayers were pulsed with ferritin (10 mg ml^{-1}) for 3 h in Leighton tubes[14]. Next day, suramin (200 μg ml^{-1}) was added to fresh medium in half the tubes and all were incubated for 6 d at 37 °C. After washing, live yeasts were added and the tubes reincubated, and the macrophages were fixed 40–50 min later[10,19].
Fig. 3 Ultrastructure of a macrophage with ferritin-labelled secondary lysosomes (L) after incubation with live yeast cells for 45 min. Ferritin label (F) surrounds a yeast cell wall (YW) inside the 'tight' phagosome membrane (P), indicating phagosome–lysosome fusion. A lysosome is seen fusing (LF).

In thin sections of controls fixed 45 min after the start of ingestion (Fig. 3), ferritin label was seen within about 80% of yeast-containing phagosomes. The phagolysosomal membrane was invariably applied closely to the surface of the enclosed yeast cell, that is, of a "tight" variety[20,21]. About
Fig. 4 Conditions as Fig. 3 but macrophages pretreated with suramin (200 μg ml^{-1}). Lysosomes (L) are labelled but ferritin is absent from zone between yeast wall (YW) and 'loose' phagosome membrane (P). Non-fusion.

half the yeasts were "granular" in appearance, suggesting incipient degradation. In suramin-pretreated macrophages (Fig. 4) the ferritin label had entered only about 10% of phagosomes; where fusion had not occurred, the phagosome membranes were almost all of a "loose" variety[20,21]. The yeast cells mostly appeared structurally intact. Autophagic vacuoles were present in a proportion of the macrophages pretreated with suramin at 200 μg ml^{-1}.

We infer that suramin does not interfere with the peri-phagosomal assembly of lysosomes, but affects the membrane fusion. Suppression of this process in leukocytes by this trypanocide has not previously been reported, and it is not clear whether any of its known properties (see refs 22–25) are relevant. Suramin is a polybasic anion and binds strongly to plasma proteins. It enters cells by endocytosis and becomes concentrated in their lysosomes. It inhibits many enzymes, including some of the lysosomal proteases, and it also inhibits (Na$^+$−K$^+$)-activated ATPase. It is anti-complementary.

The live-yeast/acridine orange system may prove useful for studying the mechanisms of phagosome–lysosome fusion in cultured macrophages, and throw light on how non-pathogenic microorganisms are inactivated and disposed of —especially whether the lysosomal enzymes actually kill, or merely digest organisms inactivated by other processes. Manipulations by means of a fusion inhibitor such as suramin should add to the usefulness of such a system.

We thank Dr J. A. Armstrong for valuable advice and criticism; and Drs D. H. Williamson and J. Williamson for technical suggestions relating, respectively, to yeast cells and suramin.

Protective tumour cell ghosts with intact membrane markers

TRANSPLANTATION antigen-like tumour-associated surface membrane antigens (TATA) have now been prepared in solubilised or semi-solubilised form[1-3]. The methods of preparation are, however, complicated and yields are usually poor. Moreover, protection experiments with solubilised tumour antigens have rarely been successful and have given very limited protection[1,2,4,5]. On the other hand, all manner of devitalised cells protect in immunisation experiments against living tumour cells[6]; and it is therefore possible that interference with cell membrane integrity during solubilisation destroys tertiary and quarternary structures important for the immunogenicity of membrane antigens[6,7]. We describe here a simple and gentle procedure for preparing in near-quantitative yield (nucleated) tumour cell 'ghosts' with retention of protective immunogenicity. Freeze drying of 'ghost' suspensions provided a stable material which retained its protective activity for 2.5 yr when stored dry at 4 °C.

Ehrlich ascites tumour cells (EATC) were obtained from BALB/c mice inoculated intraperitoneally 8–9 d previously with 10^6 viable (dye exclusion) EATC and were immediately mixed with an equal volume of Hanks' balanced salt solution (HBSS) containing 10^{-3} M EDTA, thus giving an homogeneous suspension essentially free of erythrocytes (RBC). After two washes in HBSS or Tyrode (5 min centrifugation at 1,000g followed by resuspension to the original volume of fresh solution), the cells were subjected to hypotonic shock, essentially as performed by Ponder in the preparation of RBC ghosts[8]; the EATC were suspended at a concentration of 10^8 ml^{-1} in CO$_2$ saturated water at 4 °C, held at this temperature for 10 min, centrifuged and resuspended in fresh hypotonic solution for another 10 min. After repeating this sequence, the suspension was washed four to five times with buffer (0.14 M NaCl in 0.01 M Tris, pH 7.2). Table 1 shows that about 50% of the cell protein is extracted together with all the EATC glucose-6-phosphate dehydrogenase, an enzyme known to be associated

Table 1 Recoveries of ghosts from EATC in terms of cell counts and comparisons of proteins and enzyme contents of ghosts and intact cells

	Intact EATC	Ghosts	% Recovery
Total cell counts ($\times 10^{-9}$)	1.44±0.08	1.34±0.09	93
Protein (mg per 10^9 cells)	211±21	95±30	45
Total ATPase*	191±41	194±43	100
5'-nucleotidase*	27±4	24±5	100
Glucose-6-phosphate dehydrogenase†	1.82±0.41	Nil	Nil

Ghosts can be counted as readily as intact cells and would be regarded as viable by dye exclusion although they do not form tumours when injected into mice.

*μmol phosphate liberated per h per 10^9 cells.
†μmol NADPH produced per min per 10^9 cells.

with cell cytoplasm[9]. On the other hand, ATPase$^+$ and Na$^+$ K$^+$ ATPase, enzymes occurring in association with membranes[10-12], were retained quantitatively in the ghosts. Although 5'-nucleotidase has been shown to be membrane-bound in rat liver[11,12], in EATC its activity proved to be too low to be of value as a membrane marker.

Phase contrast microscopy of the EATC 'ghosts' showed a slightly enlarged and still nucleated cell with an otherwise 'empty bag' appearance. Acridine orange (AO) staining[13,14] (using two drops of cell suspension with two drops of a 0.02%

Table 2 Quantification of membrane immunofluorescence produced by reacting fluorescein-labelled goat anti-mouse Ig with known numbers of EATC (or ghosts) incubated previously with rabbit anti-EATC serum

Rabbit anti-EATC (dilution)	Fluorimetric readings		
	Original EATC	Ghosts	Control
1:5	0.95±0.05	0.96±0.05	0.03
1:10	0.82±0.04	0.80±0.05	0.03

5 × 10^6 cells were used per test and the carefully washed fluorescent cells were finally suspended in 2 ml Tris–Triton X-100. Control cells were treated with equivalent dilutions of normal rabbit serum in place of the rabbit anti-EATC serum. Fluorimetric readings were taken within 1 h of completing the tests.

aqueous solution of AO) showed under ultraviolet light that the ghosts had retained the green-fluorescing nucleus of normal EATC. The plasma membrane and a fibre-like fine network in the cytoplasm could be seen in dull red-brown outline. The usually bright orange-fluorescing cytoplasmic granules of intact EATC, however—most likely lysosomes—had disappeared, confirming the leakage of cytoplasmic contents already indicated by the chemical and enzymic tests. Yet the original cell shape was well maintained in ghosts stored in the isotonic Tris-NaCl buffer. This, in conjunction with retention of membrane enzymes, suggests remarkable retention of structural integrity and retention of an at least partially intact membrane system. Freeze-dried ghosts had a somewhat crumpled appearance, but still showed the essential structural features.

The epitopic antigen densities of the ghosts were compared with those of the intact cells by a quantitative membrane immunofluorescent method (R.A. and L. Waft, unpublished). Briefly, aliquots of 5×10^6 washed EATC (or ghost equivalents) were first reacted with rabbit anti-EATC serum and, after three washes in Hanks' balanced salt solution (centrifugation at $1{,}000g$ for 5 min), with fluorescein-conjugated anti-rabbit IgG. After further washings the cells were finally suspended in Tris–Triton X buffer (a mixture of equal volumes of 1% Triton X-100 in water and 0.04 M Tris-HCl, pH 8.0). This yields a stable fluorescent cell suspension which can be read in a conventional fluorimeter (Aminco–Bowman). Table 2 shows that equivalent numbers of intact EATC and EATC 'ghosts' gave identical readings, whereas controls (immune serum replaced by an equivalent dilution of normal rabbit serum) gave readings of about 3% of the test readings. These tests therefore indicate retention of the full surface complement of antigens demonstrable by the rabbit anti-EATC serum used.

Retention of protective anti-EATC surface immunogenicity was further established by immunising three groups of mice respectively with X-irradiated but otherwise untreated EATC (E*)[6,15], with ghosts and with the extract concentrates from preparing the ghosts (Ex). Each mouse received two spaced (2 weeks) injections of 10^8 E* or ghosts, and the third group the extracts of twice that number of EATC. One week after the second injection all the mice were challenged with freshly collected tumour cells (viability >95% by dye exclusion), either EATC or cells from an unrelated tumour (methylcholanthrene-induced, MC). Table 3 shows that immunisation with EATC ghosts protected as well as did the E*, whereas the extracts of even twice the number of EATC provided no protection whatever. Table 3 shows that the unrelated tumour cells grew as well in the EATC-injected as in the uninjected control mice. The specificity of the reaction was confirmed by lymphoid cell transfer experiments[16]. Draining node cells from mice injected with E*, ghosts or Ex were collected 5 d after the last subcutaneous injection, mixed with 5×10^5 EATC or 10^5 MC tumour cells (lymphoid cell–tumour cell ratio 100:1) and injected subcutaneously into groups of normal mice. The control groups received the two types of tumour cells

Table 3 Protective immunisation in BALB/c mice

Immunising dose (Cell no. per subcutaneous injection)	Challenge (No. of viable tumour cells interperitoneally)	Tumour takes in:	
		Test	Control
10^8 E*	10^6 EATC	0/12	6/6
10^8 E*	10^5 MC	6/6	6/6
10^8 ghosts	10^6 EATC	1/18	6/6
10^8 ghosts	10^5 MC	6/6	6/6
Ex from 2×10^8 EATC	10^6 EATC	11/12	6/6
Ex from 2×10^8 EATC	10^5 MC	5/6	5/6

E*, X-irradiated EATC (10,000 rad).
Ex, combined concentrated EATC extracts obtained during the preparation of EATC ghosts.
MC, methylcholanthrene-induced tumour cells.

Table 4 Lymphoid cell transfer tests

Lymphoid cells from mice immunised with:	Admixed tumour cells	Tumour takes in:	
		Test	Control
E*	5×10^5 EATC	1/12	6/6
Ghosts	5×10^5 EATC	0/6	6/6
Ghosts	10^5 MC	6/6	6/6
Ex	5×10^5 EATC	6/6	3/3

Lymphoid to tumour cell ratio in the injected mixtures, 100:1.

alone. Table 4 shows that EATC tumour formation, but not MC tumour formation, was prevented by lymphoid cells from mice immunised with E* or EATC ghosts. As expected, lymphoid cells from mice immunised with Ex failed to prevent EATC tumour formation.

The fact that an essentially cytoplasm-free nucleated cell membrane bag has been found quantitatively to retain surface antigens of the intact cell and has proved fully immunogenic in protection experiments, whereas the cytoplasmic cell sap has proved completely inactive, suggests that (at least in EATC) TSTA (or TATA) are closely and probably exclusively associated with the plasma (and possibly other) cell membranes, whereas the cytoplasm is free of TSTA (TATA). Ghosts of the type prepared here may prove useful not only for protective immunisation, but also as a more satisfactory starting material than intact cells in cell-antigen purification. A fully immunogenic intermediate of this type may also help clarify features involved in preserving protective tumour immunogenicity during purification.

Enhanced immunological surveillance in mice heterozygous at the H-2 gene complex

THE major histocompatibility (H) antigens of higher animals show extreme genetic polymorphism equalled, in higher vertebrates, only by that associated with the immunoglobulins[1]. Maintenance of such a high rate of variability implies

evolutionary advantage for heterozygotes in the HL-A system for man, or at the H-2 gene complex in mice[2,3]. We propose a possible selective mechanism, based on the realisation that immunological surveillance function (defined here as recognition and elimination of modified host cells by sensitised thymus-derived lymphocytes (T-cells) may be considerably enhanced in mice heterozygous at the H-2 gene complex.

This idea arose from experiments with two of the most prevalent naturally occurring virus infections of mice, lymphocytic choriomeningitis (LCM) and ectromelia (mouse pox). In both diseases immune T cells seem to be sensitised to altered self antigens[4-7], the self components involved being specified at, or near to, either of the two loci (H-2K or H-2D) coding for the major transplantation antigens. Whether viral and H-2 components are in some way complexed, or more long range modification of H-2 antigens is induced by the infectious process, is neither known nor central to the present argument.

Table 1 Cytolytic activity of LCM-immune spleen cells for H-2[k] virus-infected L cells, or L-929 fibroblasts

Mouse strain	H-2K	H-2D	Lytic units*	% Activity
CBA/H	kk	kk	6.5×10^4	100
CBA/H × C57BL F$_1$	kb	kb	9.0×10^4	72
B10.A	kk	dd	16.0×10^4	40
C57BL	bb	bb	$> 1,000 \times 10^4$	< 1

* Number of LCM-immune spleen cells necessary to cause 33% specific ^{51}Cr release from 5×10^4 (cells per assay well) LCM virus-infected targets[4,8]. Mice were injected intravenously with 2,000 LD$_{50}$ WE3 LCM virus 8 d before.

The evidence for this 'altered self' hypothesis is as follows[4-7]: First, lysis of LCM virus-infected targets by sensitised T cells occurs only if the two cell types are compatible for either one parental H-2 haplotype, or at H-2K or H-2D. Identity of immune response genes (I region) is neither sufficient nor necessary. Second, results of selective proliferation studies *in vivo* and 'cold-target' competitive inhibition experiments *in vitro* indicate that F$_1$ mice generate LCM-immune T cells of at least two specificities, each directed against altered self characteristics of one parental H-2 haplotype. Third, similar experiments using H-2 recombinant mice also show that homozygotes possess a minimum of two T cell specificities, associated with H-2K or H-2D. Heterozygotes would thus generate T cells of at least four specificities, sensitised to altered self antigens coded for at the H-2K and H-2D loci of each parental haplotype. The total range of the T cell response in the F$_1$ may thus be

Table 3 Susceptibility of H-2 different mice sharing the C57BL genetic background

†, $P > 0.05$.
‡, $P < 0.001$.

as much as twice that possible in either parental homozygote.

Comparison of cytotoxic T cell activities *in vitro* provides support for this concept. Repeated experiments have shown that compatibility (between T cell and target cell) at one H-2 haplotype confers at least 70% of the cytolytic capacity found in the homozygous situation[4] (that is, full compatability between homozygous killer T cell and target cell). Results for some of the mouse strains used in the *in vivo* experiments described below are shown in Table 1. The possible response in the F$_1$ associated with both haplotypes could thus be in excess of 140% of that occurring in either parent.

Enhanced T cell responsiveness in F$_1$ mice may also be shown *in vivo*. The LCM model used here is paradoxical in so far as our general argument is concerned, as it reflects a fatal immunopathological process directed against virus-infected cells in the central nervous system. The same response to virus growing in lung and liver results in immune elimination and recovery[9], the normal consequence of cell-mediated immunity[10]. Mice injected intracerebrally with a low dose of viscerotropic (WE3) LCM virus die with severe neurological symptoms in 7–9 d. Death seems to reflect damage to virus-infected meningeal and choroid plexus cells caused by H-2 compatible immune T cells[5,11], LCM virus itself being of minimal pathogenicity. Inoculation of a large dose of viscerotropic virus intracerebrally, however, often results in survival. An explanation for this seemingly high dose paralysis[12,13] is that administration of large amounts of virus leads to more extensive growth in viscera, with resultant recruitment of sensitised T cells to peripheral sites and reduced neuropathology mediated by T cells.

Heterozygotes were consistently more susceptible than were parental homozygotes to intracerebral inoculation with WE3 LCM virus, the effect being apparent at all dose

Table 2 Susceptibility of parental and F$_1$ mice to intracerebral WE3 LCM virus

C57BL	$3.6 \pm 0.2\ddagger$	$4.1 \pm 0.1\S$	4.1 ± 0.1
C57BL × CBA/H F_1	$4.2 \pm 0.1\ddagger$	*$4.6 \pm 0.1\S$	NS
CBA/H	$3.4 \pm 0.2\ddagger$	$4.3 \pm 0.1\dagger$	4.1 ± 0.1

Mice were injected intracerebrally with 10^3 LD_{50} of WE3 LCM virus. Samples of cerebrospinal fluid (CSF) were obtained from the cisterna magna, stained with WBC diluting fluid and counted. CSF of CBA/H mice injected intracerebrally with diluent 6 d previously contains < 100 cells μl^{-1} (ref. 5).
NS, Not sampled, as no mice surviving.
* In 8 of 12 mice sampled brain swelling, the severity of which is directly related to progression of both symptoms and the inflammatory lesion[5], was so advanced that CSF could not be obtained.
Differences between parental and F_1 mice: $\dagger$, $P < 0.02$; $\ddagger$, $P < 0.01$; $\S$, $P < 0.001$.

levels tested (Tables 2 and 3). Furthermore, the inflammatory response, which is largely produced by T cells and is directly related to severity of symptoms[4,5], was both more rapid and of greater magnitude in F_1 mice (Table 4). This somewhat artefactual system serves, therefore, to illustrate that the T-cell response to virally modified cells is enhanced in heterozygotes.

Results from both *in vitro* and *in vivo* systems thus support the concept that immune responsiveness is enhanced by involvement of a greater number of T-cell specificities, directed against altered self antigens coded for at H-2K or H-2D. Such an argument provides a mechanistic basis for evolutionary advantage of both gene duplication and heterozygosity at the H-2 gene complex, in the absence of positive selection for any particular H-2 haplotype.

Specific basophil hypersensitivity induced by skin testing and transferred using immune serum

INTRADERMAL skin testing of appropriately immunised guinea pigs results in specific hypersensitivity reactions of the 24 h delayed type. As controls, we routinely skin test non-immune animals. We have found that skin testing itself can cause specific sensitisation for delayed time course reactions in normal guinea pigs. Skin testing non-immunised animals with the protein antigen keyhole limpet haemocyanin (KLH) leads, within several days, to striking macroscopic lesions at these primary (1°) injection sites in all animals. We have termed these responses 'flare reactions', and have found on histological examination that they contain large accumulations of basophils. Overall, these flares resemble hypersensitivity reactions with a delayed time

course termed 'cutaneous basophil hypersensitivity' (CBH)[1]. As proof that skin testing *per se* can specifically sensitise, we obtained serum from animals with these cutaneous basophil flare reactions and carried out intravenous transfers to non-immune recipients who then received a KLH skin test. Delayed 24 h CBH reactions which were specifically elicited by this native protein antigen, were uniformly transferred by immune serum.

Two separate preparations of KLH (Pacific Bio-Marine, Venice, California) were used for these studies. Hartley strain albino guinea pigs (250–300 g) were bred at the Division of Animal Care at Yale University School of Medicine. On day 0 animals were flank skin tested by intradermal injection of 200 μg KLH in phosphate buffered saline (0.1 ml) at one site. These primary injection sites were observed daily and macroscopic skin reactions were noted at 4 d in half of the animals, were present in all 40 of the animals at 5 d, and reached a peak at 6 d (Fig. 1). These reactions were erythematous, indurated, and seemed tender to the touch. Animals initially injected with 20 and 200 μg KLH at separate sites also had macroscopic reactions at the 20 μg site, which were maximal 6 d after intradermal injection (Fig. 1).
Fig. 1 Guinea pig macroscopic skin reactions at sites injected with KLH: □, 20 μg; ○, 200 μg. Primary (1°) intradermal injections were at day 0, and were read daily. Secondary (2°) injections were at day 6 and were read 24 h later.

Secondary (2°) skin tests with 20 and 200 μg KLH on the contralateral flank at day 6, resulted in large erythematous and weakly indurated reactions which began at about 4–6 h and reached a peak at 12–24 h. At this time, the 7-d-old 200 μg priming site occasionally showed superficial crusting and sloughing, and less erythema and induration than on the previous day. Histologically, this primary site (Fig. 2) and contralateral 24 h secondary skin test reactions to 200 or 20 μg KLH all had large infiltrates of basophils (Table 1) in addition to many mononuclear cells and some eosinophils. The site of skin testing performed 7 d previously with 20 μg KLH also showed CBH. It was concluded that intracutaneous injection of KLH sensitised guinea pigs for CBH, and that sufficient quantities of this antigen may have been retained at the skin test site to result in a flare of CBH at the priming site.

Table 2 shows the results of four separate experiments demonstrating serum transfer of CBH using donor animals which were immunised by intradermal injection of KLH and manifested cutaneous basophil flare reactions. Three different serum pools resulting from bleeding 7 d after priming were used for intravenous transfer of 2 ml per recipient. Two hours after transfer, recipients were skin tested with 200 μg KLH. In all four experiments, examination of these test sites showed that KLH immune sera from skin test-sensitised animals transferred macroscopic delayed (24 h) reactions containing large basophil infiltrates. Suc-

Table 1 Cutaneous basophil flares and 24 h cutaneous basophil reactions induced by intradermal injection of KLH

Time after initial injection (No. of animals)	Skin test dose	Macroscopic erythema (mm)±s.e.	Microscopic basophils* ±s.e.
Flare reactions at priming site:			
24 h (16)	200 µg	0	4±1
48 h (6)	200 µg	0	3±1
7 d (7)	200 µg	9±1	203±37
7 d (4)	20 µg	4±2	71±23
24 h CBH reactions at 6 d secondary skin test site:			
7 d (13)	200 µg	14±1	103±20
7 d (10)	20 µg	7±1	85±18

*Skin reactions were fixed in Helly's solution, embedded in paraffin and Giemsa stained for basophil identification[2]. Basophils were counted in five central and adjacent 180 µm diameter oil immersion (×1,000) fields at the uppermost dermis.

cessful CBH transfers were also accomplished with 1 week sera from KLH-primed donors which did not receive secondary skin tests. Control recipients of KLH immune sera which were intradermal skin tested with sheep red blood cells (SRBC) (5% or 20%) or irrelevant proteins (oxazalone or picryl human albumin, 200 µg) showed no macroscopic reactions and no basophil infiltrates. KLH skin tests (200 µg) in a variety of controls which received heterologous immune sera, media with 10% foetal calf serum (FCS), or nothing, also caused no macroscopic reactions and no basophil accumulations at 24 h (Table 2). It was concluded that skin tests can cause specific sensitisation for a reaction of the delayed type, that serum transfers of CBH to a native protein antigen can be achieved; and that serum factors contribute to cutaneous basophil flare reactions.

Our work has pointed out that serum factors are important in some delayed reactions containing significant basophil infiltrates. Thus, a component of some delayed basophil-containing reactions is hapten-specific[2,3], and is transferable by small quantities of immunochemically purified antibody recovered in 7S IgG$_1$ column fractions[4]. Antibody alone, however, is not the sole factor responsible for all delayed basophil infiltrates. We have shown that carrier-specific basophil accumulations are probably mediated by T cells[5]. Thus, B cell-derived antibodies and T cells probably function in the arrival of basophils in delayed cutaneous reactions.

Our previous studies of serum-transferred hapten-specific CBH necessarily involved sensitisation and testing with synthetic haptens conjugated to proteins and also used immunisation with adjuvants. In the present study, CBH sensitisation and accompanying cutaneous basophil flares were achieved by intradermal injection of a native protein without adjuvants. Serum obtained from these animals uniformly transferred specific delayed reactions, which were macroscopically evident in the flank skin of recipient guinea pigs, and showed numerous basophils on microscopic examination.

Jones and Mote originally described the ability of skin tests to sensitise humans for delayed reactions, and they noted flares at the primary site in nearly one third of individuals immunised by intradermal injections of hetero-

logous proteins[6,7]. This study with guinea pigs has shown that cutaneous flares at sites of intradermal immunisation are characterised by marked basophil accumulations; we have also noted flares of basophils containing cutaneous reactions following intradermal sensitisation of humans with KLH (P.W.A. and J. E. Atwood, unpublished). In human contact reactions, which also have basophil accumulations[1], similar flares occur at primary sensitisation sites, and flares at human skin sites primed with dinitrochlorobenzene are considered the strongest criterion of normal immune reactivity[8].
Fig. 2 Electron photomicrograph from a primary skin test site from a non-immune guinea pig injected 7 d previously with 200 µg KLH. A dense infiltrate of basophils is seen in the upper dermis. ×4,200.

A consideration of the ability of skin tests to sensitise is pertinent to the interpretation of specific immune reactivity following transfer of serum, cells or cell extracts (such as transfer factor, which may transfer specific immunity or act as an adjuvant[9]). It is possible that a successful transfer may in some instances depend on the ability of the transfer to augment and accelerate the sensitising or irritating potential[10] of the skin test used to demonstrate the transfer. In systems in which flares can develop from skin testing, interpretation of the specificity of passively acquired

Table 2 Serum transfer of CBH to KLH following intradermal (i.d.) immunisation

Serum donor immunisation	Number of: Experiments	Recipients	Material transferred	Recipient 24 h skin test reaction (200 µg KLH) Erythema (mm)	Basophils*
KLH (200 µg i.d.)	4	15	2 ml sera	7±0.7	82±10
1% SRBC+IFA	1	5	2 ml sera	1	7
CFA	1	5	4 ml sera	0	7
None	1	3	10% FCS	0	0
None	2	6	Nothing	0	9

*See legend to Table 1. IFA and CFA, incomplete and complete Freund's adjuvant.

immunity can depend solely on an accelerated development of reactions in the first skin tests of recipients. The serum transfer of basophil sensitivity to KLH reported here was validated by the absence of reactions to various irrelevant antigen skin tests in recipients of KLH immune sera, and also by the absence of macroscopic and microscopic delayed changes to KLH skin testing in non-immune animals and recipients of heterologous immune sera. Within the context of these controls, we conclude that serum transfer of CBH to KLH can be achieved.

Dependence of the contractile activation of skinned cardiac cells on the sarcomere length

FRANK[1] and Starling[2] have demonstrated that the systolic pressure developed by the heart decreased as its diastolic volume was altered in either direction from an optimum value. This law has been explained by variations of the number of cross bridges between the thin (actin) and the thick (myosin) filaments which generate force in individual cells[3,4] in accordance with the sliding filament theory[5].

Recent studies on skeletal muscle suggest that the release of Ca^{2+} from the sarcoplasmic reticulum (SR), which links the action potential of the surface membrane (sarcolemma) to the activation of the myofilaments, may also depend on the length of the cell. The activation of the myofilaments was found inhomogeneous at short sarcomere length (SL)[6] except when the fibre was treated with caffeine[7]. Furthermore, less Ca^{2+} was released at shorter length in fibres injected with the Ca^{2+}-bioluminescent protein aequorin[8,9]. The mechanism of the decrease in Ca^{2+} release, however, was not defined and no experiment was carried out on cardiac cells.

We have developed a simplified preparation to define the influence of SL on both the force developed by the myofilaments and the release of Ca^{2+} by the SR in cardiac cells. First, we have used single cells, thus eliminating the connective tissue which renders the relationship between the SL of each cell and the length of the preparation unpredictable[10]. Secondly, we have removed the sarcolemma of these cells by microdissection, thus placing the myofilaments and the SR in direct contact with solutions.

Cardiac tissue from the adult rat ventricle was homogenised into broken single cells (less than 60 µm in length and 15 µm in width) in a relaxing solution (composition given in Fig. 1). The remaining pieces of sarcolemma were removed from a broken cell by microdissection in a perfusion chamber placed on the stage of an inverted Reichert microscope[11]. The ends of the sarcolemma-free ('skinned') cell were impaled in a direction perpendicular to the axis of the myofibrils with two glass microtools. One microtool was immobilised and the other was connected to a highly sensitive photodiode isometric transducer[12]. The SL was measured on photomicrographs and on motion picture frames (100–400 f.p.s.) taken under differential interference microscopy (×160 objective with 1.30 numerical aperture) on at least 20 sarcomeres of each cell during both relaxation and contraction.

The concentration of Ca^{2+} ions (free $[Ca^{2+}]$) in the perfusing solutions was buffered with ethyleneglycol-*bis* (β aminoethyl ether) *N,N'*-tetraacetic acid (EGTA). We have previously demonstrated that two types of contractions can be obtained in this preparation[11]. The tonic contractions developed by the skinned cells when the free $[Ca^{2+}]$ is increased in the presence of a large buffer capacity (that is, a high total [EGTA]) correspond to the direct activation of

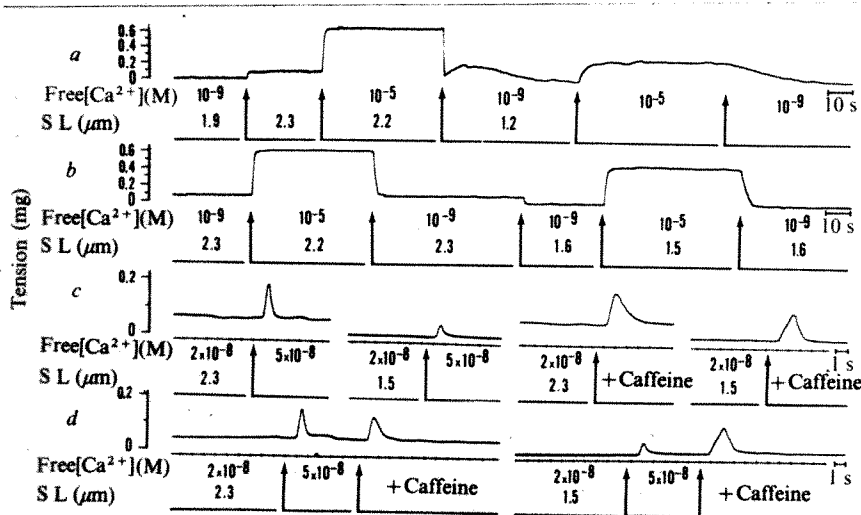
Fig. 1 Arrows indicate changes of free $[Ca^{2+}]$ or of SL. When one parameter was not modified the corresponding case was left unlabelled. A single cell was used to obtain the tracing of each row. The lengths of the cells were 45–55 µm when they were stretched to a 2.3 µm SL in relaxing solution. Their widths were: *a*, 12 µm; *b*, 11 µm; *c*, 11 µm; and *d*, 9 µm. SLs shorter than 1.5 µm were inferred from the variations of the distance between predetermined points of the cell. Striations caused by contraction bands, however, were visible at these short lengths. The total [EGTA] was 4×10^{-3} M in *a* and *b* and 5×10^{-5} M in *c* and *d*. All media contained 7 mM glucose and 18 mM Tris maleate, pH 7.0; temperature was maintained at 22 °C. The concentrations of Na_2EGTA, $CaCl_2$, Na_2ATP and $MgCl_2$ were varied to obtain the desired free $[Ca^{2+}]$, whereas the free $[Mg^{2+}]$ was held constant at 3.16×10^{-4} M and [MgATP] at 3.16×10^{-3} M. The ionic strength was kept constant at 0.16 M by appropriate addition of KCl. The following apparent association constants were used at pH 7.0: CaEGTA 4.9×10^6 M^{-1}, MgEGTA 40 M^{-1}, CaATP 5×10^3 M^{-1}, MgATP 11.4×10^3 M^{-1}. The amplitude of the tonic contractions was maximum for 10^{-5} M free Ca^{2+} and zero for a free $[Ca^{2+}]$ smaller than 2×10^{-7} M in the presence of 4.0 mM total EGTA. In contrast, phasic contractions could be triggered by a free $[Ca^{2+}]$ as low as 4×10^{-8} M in the presence of 5×10^{-5} M total EGTA. A suprathreshold free $[Ca^{2+}]$ (5×10^{-8} M) was used to trigger the phasic contractions in this study.


Fig. 2 Effects of the variations in SL (measured during contraction) on tonic contractions induced by direct activation of myofilaments (■) and on the phasic contractions induced by a release of Ca^{2+} from the SR triggered either by Ca^{2+} (●, △) or by caffeine (○). Tensions (plateau of tension for the tonic contractions or peak tension for the phasic contractions) were measured as percentages of tension developed by the same type of contraction at a 2.2 μm SL_x(□). Each point represents the mean of 12–15 measurements ,and each vertical bar represents 1 s.d. (shown in only one direction for clarity). Lengths of the cells were 41–63 μm when they were stretched to a 2.3 μm SL in relaxing solution. Their widths were 10±2 μm except for △, for which the widths of the cells were 5±1 μm.

the myofilaments by the Ca^{2+} present in the buffer (Fig. 1*a* and *b*). In contrast, the phasic contractions triggered by a small variation of the free $[Ca^{2+}]$ in the presence of a slight EGTA buffering correspond to a Ca^{2+}-triggered release of Ca^{2+} from the SR (Fig. 1*c* and *d*). By this mechanism, a small trans-sarcolemmal influx of Ca^{2+} into the intact cell would trigger a release of Ca^{2+} from the SR sufficient to activate the myofilaments[11].

The effects of SL on the tonic contractions by direct activation of the myofilaments were studied in the presence of 4×10^{-3} M total EGTA (Fig 1*a* and *b*). The slack SL in relaxing solution was 1.9 μm (Fig. 1*a*). A larger SL (2.3 μm) was obtained by stretching the cell, which resulted in the development of a resting tension. A large active tension was induced by full activation with 10^{-5} M free Ca^{2+}. To obtain SLs much shorter than the slack SL, the cell was released by rapidly moving the end not attached to the transducer, and a relaxing solution was applied (Fig. 1*a*). A rapid relaxation followed by a slow redevelopment of tension and a slow relaxation were observed without change of length and without variation in the spacing of the contraction bands observed at this short SL. When the relaxation was completed the contracting solution was applied, and a plateau of tension was slowly reached with no significant variation in SL (<0.5 μm). To obtain SLs moderately shorter than the slack SL, one end of the cell was simply compressed during relaxation (Fig. 1*b*) causing a

waving of the myofibrils, which became straight during contraction.

The compliance of the transducer (2–3 μm mg^{-1}) and the passive lengthening of damaged tissue in the areas of attachment to the microtools enabled a significant shortening of the SL to occur during contraction. Accordingly, the active tension was expressed as a function of the SL measured during the contraction rather than during the relaxation (Fig. 2). The maximum tonic tension was observed at a 2.2 μm SL and was defined as 100% tension in each cell. The tension obtained at other SLs was expressed as a percentage of this maximum value. Tensions of 58±10% (s.d.) at a 1.2 μm SL and of 78±7% at a 1.5 μm SL were obtained. These results are similar to those observed on skinned fibres of skeletal muscle[13] and are very different from those observed in the intact cardiac muscle where no active tension is developed at a length 30% below optimum[3,4]. Therefore, the Frank–Starling law[1,2] cannot be explained entirely by a dependence of the maximum number of cross bridges between the thin and the thick filaments on the SL.

The effects of SL on the phasic contractions induced by Ca^{2+} released from the SR were studied in the presence of 5×10^{-5} M total EGTA (Fig. 1*c* and *d*). Short SLs were obtained by the same procedures as for the tonic contractions but with a relaxing solution containing 5×10^{-5} M total EGTA and 2×10^{-8} M free Ca^{2+}. The amplitude of these contractions decreased rapidly when the SL was decreased. It was maximum at a 2.3 μm SL (102±3% of the tension developed at a 2.2 μm SL which was chosen arbitrarily as reference) and only 32±11% at a 1.5 μm SL (Figs 1*c* and 2). The activation of the cell was homogeneous at a 1.5 μm SL, as demonstrated by the absence of wavy myofibrils during contraction. Furthermore, no significant differences were observed in the results obtained in preparations of various widths (5±1 μm compared with 10±2 μm; Fig. 2). These observations suggest that the Ca^{2+} present in the buffer diffused homogeneously throughout the cells.

Phasic contractions were also triggered by 5×10^{-3} M caffeine (Fig. 1*c*), which releases a large fraction of the Ca^{2+} contained in the SR (ref. 14). When the SL was decreased from 2.2 to 1.4 μm the percentage decrease in amplitude of these caffeine-induced contractions was not significantly different from that of the tonic contractions elicited by the direct activation of the myofilaments (Fig. 2). This suggests that the amount of Ca^{2+} released by caffeine and the Ca^{2+} content of the SR (by inference) are not dependent on the SL in this range of SLs. A contraction was induced by 5×10^{-3} M caffeine at a fixed interval after the contraction induced by Ca^{2+}-triggered release of Ca^{2+} (Fig. 1*d*). By this method[15], the amount of Ca^{2+} remaining in the SR after the Ca^{2+}-triggered release can be unmasked. The contraction induced by caffeine at a 1.5 μm SL (after the small Ca^{2+}-triggered contraction) was larger than that induced at a 2.3 μm SL (after the large Ca^{2+}-triggered contraction) Thus, a decrease in SL would not decrease the Ca^{2+} content of the SR but would decrease the amount of Ca^{2+} released by the Ca^{2+}-triggered process. Furthermore, the slow rate of tension development and the relatively rapid relaxation, which were consistently observed in the contractions induced by caffeine at short SLs, may be related to a decrease in rate of Ca^{2+} release with no modification or even an increase in rate of Ca^{2+} sequestration by the SR.

The amplitude of tonic and phasic contractions decreased when the SL was increased above 2.2 or 2.3 μm (Fig. 2), in agreement with the sliding-filament theory[5]. The apparent discrepancy between this finding and that reported in partially activated skinned fibres of skeletal muscle[16] will not be discussed because SLs larger than 2.5 μm were not used in the data reported here.

In conclusion, these results suggest that decreasing the SL

below optimum results in a partial inhibition of the process of Ca^{2+}-triggered release of Ca^{2+} from the SR of cardiac cells. This mechanism may contribute to the explanation of the Frank–Starling law of the heart[1,2].

Morphine antagonises prostaglandin E₁- mediated inhibition of human platelet aggregation

COLLIER and Roy[1] have proposed that in morphine-sensitive neurones the receptor site may be adenyl cyclase, which is physiologically stimulated by prostaglandin E_1 (PGE_1) and pharmacologically blocked by opiates. An hypothesis has been put forward that morphine exerts its analgesic effect by inhibiting the stimulation by PGE_1 of cyclic AMP formation in appropriate neurones[2], whereas acute side effects of opiates may be caused by stimulation of prostaglandin biosynthesis[3].

We wondered if a similar receptor site for PGE_1 and morphine exists in blood platelets. The basis for this assumption is that inhibition of platelet aggregation by PGE_1 (refs 4 and 5) and PGE_2 (ref. 5) is associated with activation of adenyl cyclase and accumulation of cyclic AMP in platelets. Therefore the final effect of PGE on platelets (that is, aggregation) is mediated through the same biochemical pathway as some central effects of PGE (for example, pain sensation). Moreover platelets have the enzymic system that synthesises prostaglandins[6,7].

Platelet aggregation was studied by the turbidometric technique of Born[8]. Methods for blood collection of citrate platelet-rich plasma (PRP) and platelet-poor plasma (PPP) were as described by Han and Ardlie[9]. PPP was used to adjust the platelet count of PRP to 250,000 μl^{-1}. The aggregating agents used were ADP (Sigma) at a final concentration of 2 μM and DL(±)-adrenaline bitartarate (Sigma) at a final concentration of 50 μM.

Preincubation of PRP with PGE_1 (Upjohn) at a final concentration in the range 0.028–0.565 μM inhibited adrenaline-induced aggregation in a dose-dependent manner. PGE_1 was added to PRP 30 s before adrenaline. Then PGE_1 flattened the slope of the first phase and delayed the appearance of the second phase of aggregation. A short

(30-s) preincubation of PRP with morphine hydrochloride (Polfa) at concentrations in the range 1.33–26.6 μM reduced or abolished the protective action of PGE_1 against adrenaline-induced aggregation (Fig. 1). In some platelet preparations PGE_1 caused a complete disappearance of the second phase of aggregation. In these preparations, preincubation with morphine restored the aggregating power of adrenaline. Usually the optimal active concentration of morphine was in the range 1 33–13.3 μM. Higher concentrations than the latter often produced a paradoxical reappearance, or even enhancement of PGE_1-dependent inhibition of adrenaline-induced platelet aggregation (Fig. 1). Some experiments with levorphanol hydrochloride (Dromoran, Roche) have shown that 5–20 times lower concentrations of the drug were needed to reach an effect equivalent to that of morphine. Incubation of PRP with morphine (26.6 μM) for up to 5 min neither changed the turbidity of PRP nor influenced markedly adrenaline-induced aggregation. In case of a distinct biphasic curve of the adrenaline-induced aggregation, morphine (2.66–26.6 μM) either shortened or erased the intercept between both phases.

The patterns of inhibition by PGE_1 of ADP-induced aggregation were somewhat different from those observed for adrenaline. Thus, PGE_1 not only reduced the rate and intensity of aggregation but also gave rise to a delay between the addition of ADP and the onset of aggregation. All these PGE_1-mediated protective effects against ADP-induced aggregation were reduced or abolished by a preincubation of PRP with morphine (Fig. 2). In the absence of PGE_1, morphine (26.6 μM) did not influence ADP-induced aggregation.

The ability of PGE_1 to inhibit aggregation varied greatly in different platelet donors. Similarly, the potency of the antagonistic action of morphine against PGE_1-mediated

Fig. 1 Prevention by morphine of the anti-aggregating effects of PGE_1 in adrenaline-induced aggregation of human PRP. For the control (*a*) 0.1 ml adrenaline bitartarate solution was added to 1.7 ml PRP and 0.2 ml distilled water, to yield a final concentration of 50 μM of adrenaline. To show the anti-aggregating effect of PGE_1 (*d*), 30 s before adrenaline was added, 0.1 ml sodium salt of PGE_1 was instilled into 1.7 ml PRP and 0.1 ml distilled water. The final concentration of PGE_1 was 0.028 μM. The antagonism between morphine and PGE_1 is shown in *b* and *c*. Morphine hydrochloride in a volume of 0.1 ml was added to 1.7 ml PRP 30 s before PGE_1, and 60 s before adrenaline. The final concentrations of morphine were 2.66 μM (*b*) and 26.6 μM (*c*). With a rise in morphine concentration the diminution of its preventive action was observed. Morphine at a concentration of 133 μM (not shown) actually enhanced the anti-aggregating effect of PGE_1.
Fig. 2 Prevention by morphine of the anti-aggregating effects of PGE_1 in ADP-induced aggregation of PRP. The procedure was similar to that described in Fig. 1. Instead of adrenaline, ADP was used at a final concentration of 2 µM. PGE_1 was used at a final concentration of 0.14 µM. *a*, ADP; *b*, morphine (26.6 µM) $+PGE_1+ADP$; *c*, morphine (2.66 µM)$+PGE_1+ADP$; *d*, PGE_1 $+ADP$. A rise in morphine concentration enhanced the preventive action of morphine against the anti-aggregating effect of PGE_1.

protection of adrenaline-induced or ADP-induced aggregation differed from one plasma to another.

Summing up, the antagonism between PGE_1 and morphine similar to that described in rat brain homogenates[1,2] may also be demonstrated in human platelets. It is probable that adenyl cyclase is the common target for PGE_1 and morphine in platelets as it is in neurones[2]. One of the common side effects of opiates is histaminaemia[10]. Basophils[11] and mast cells, like platelets[4,5], have adenyl cyclase which is stimulated by PGE_1. Because of this, PGE_1 inhibits histamine release from basophils[11] and mast cells[12]. Perhaps morphine blocks this PGE_1-mediated, protective mechanism and therefore histaminaemia appears.

It may be possible to use the preventive effects of opiates against the anti-aggregating action of PGE_1 for *in vitro* screening of potency of narcotic analgesics, as well as for the study on the character of opiate receptors[13].

Morphine elevates levels of cyclic GMP in a neuroblastoma X glioma hybrid cell line

THE use of cell lines derived from tumours of the nervous system as models for both neurones and glia has become well established. Clonal lines derived from mouse neuroblastoma C1300 have been shown to possess many properties characteristic of neurones[1]. Several such properties are more strongly expressed in hybrids between mouse neuroblastoma and rat glioma cells[2-4]. They contain choline acetyltransferase[2-4], clear and dense core vesicles[5] and dopamine-β-hydroxylase[4]. In the presence of prostaglandin E_1 (PGE_1) the hybrid cells strongly increase their intracellular levels of cyclic AMP^6. The effect of PGE_1 is antagonised by noradrenaline[7], acetylcholine[8] and morphine[9-11]. The latter finding is in agreement with that in brain homogenates[12]. In addition, morphine receptors could be detected in the hybrid cells[13].

Fig. 1 Stimulation by morphine of the levels of cyclic GMP in the hybrid line 108CC15. Cells were grown in plastic dishes (Greiner, 8.5 cm diameter)[6,15]. One hour before the experimental incubations in the presence of morphine, the growth medium was replaced by the incubation medium[15]. Morphine was added as described[10] and the incubation ended 10 min later with the removal of the medium and addition of 3 ml ice-cold 8% (w/v) trichloroacetic acid. For control of recoveries, tritiated cyclic AMP and cyclic GMP were added. For removal of the acid, the solution was extracted 5 times with ether. The cyclic nucleotides were separated on a column of BioRad AG 1×2 (Cl$^{-200-400}$ mesh, 4×0.5 cm). After application of the sample, the column was washed with 10 ml H_2O and eluted with 6 ml 0.05 mol l^{-1} HCl (cyclic AMP) and subsequently another 6 ml 0.5 mol l^{-1} HCl (cyclic GMP). After neutralisation with 3 mol l^{-1} Tris base, the cyclic GMP fraction was rerun on regenerated columns, to remove traces of cyclic AMP. After lyophilisation, the eluates were analysed for cyclic AMP and cyclic GMP. The results are mean values ±s.d. of data obtained from 4 parallel plates. Passage number 15; 1.2×10^6 viable cells per plate; viability 92%. ●, cyclic GMP; ○, cyclic AMP.
In view of the opposing effects of cyclic AMP and cyclic GMP[14], we studied the levels of cyclic GMP in the hybrid cells in response to morphine. After incubation (10 min) in the presence of the drugs under study, the cyclic nucleotides were extracted from the cells by trichloroacetic acid and separated by anion exchange chromatography. Cyclic AMP[15,16] and cyclic GMP (P. Wunderwald, D. van Calker, R. G., J. T. and B. H., unpublished) were determined by protein binding assays.

It can be seen in Fig. 1 that morphine (0.1 to 10 μmol l^{-1}) elevates cyclic GMP levels and that there seems to be a concomitant depression in basal levels of cyclic AMP. At higher morphine concentrations (0.1 to 1 mmol l^{-1}) this elevation is reversed to cyclic GMP values below those found in the absence of morphine and accompanying this there is a rise in cyclic AMP levels. The intracellular concentrations of cyclic GMP are about one order of magnitude lower than those of cyclic AMP and the absolute changes are much smaller for cyclic GMP than for cyclic AMP.

Naloxone, a potent antagonist of the action of morphine[17] inhibits the elevation of cyclic GMP levels produced by morphine (Fig. 2). With naloxone concentrations two orders of magnitude lower than those of the morphine used as stimulant, levels of cyclic GMP are reduced below basal (Fig. 2). In the absence of morphine, naloxone decreases cyclic GMP and increases cyclic AMP (Fig. 2) levels, but such changes occur at concentrations (0.1 to 1.0 mmol l^{-1}) much higher than those necessary to reduce cyclic GMP levels elevated by morphine.

The elevation by morphine of cyclic GMP levels could be mimicked by levorphanol, a congener of morphine, but not by its inactive enantiomer dextrorphan (Fig. 3). Cyclic GMP levels were increased at levorphanol concentrations of 0.1 to 10 μmol l^{-1}. An inhibition of this increase occurred at higher concentrations (Fig. 3). In response to levorphanol, the level of cyclic AMP changes inversely to that of cyclic GMP (Fig. 3). At high concentrations, dextrorphan reduces the basal level of cyclic GMP, while

Fig. 2 Naloxone inhibits the elevation of levels of cyclic GMP caused by morphine. 1.4×10^6 viable cells per plate (passage number 17, viability 90%) were incubated at varying concentrations of naloxone in the presence (●) and absence (■; ○) of morphine (10 μmol l^{-1}). ● and ■, cyclic GMP; ○, cyclic AMP.
Fig. 3 Effect of levorphanol and dextrorphan on levels of cyclic GMP and cyclic AMP. Cells were incubated with levorphanol (curves a and c) or dextrorphan (curves b and d). Curves a and b, cyclic GMP; curves c and d, cyclic AMP. Passage number 12; 1.2×10^6 viable cells per plate, viability 91%. The level of cyclic GMP in the presence of 10 μmol l^{-1} morphine was 2.9 ± 0.2 pmol mg^{-1} protein.

it elevates the level of cyclic AMP (Fig. 3). In two ways the elevation by morphine of levels of cyclic GMP in the hybrid line was demonstrated to be a specific opiate action. It was antagonised by naloxone, and mimicked by levorphanol but not dextrorphan. An analogous specificity was found for the inhibition by opiates of the elevation of cyclic AMP levels by PGE$_1$[7,10]. The doses of morphine required for a 50% increase of the cyclic GMP level (Fig. 1) and a 50% depression of the cyclic AMP level[10] agree within one order of magnitude. This similarity could suggest that the depressing effect of morphine on cyclic AMP levels[7,9,10] is perhaps mediated by cyclic GMP. In the hybrid cells noradrenaline and acetylcholine, like morphine, lower cyclic AMP levels[7-10] and increase levels of cyclic GMP (R. G. and B. H., unpublished). The negative regulatory influence of cyclic GMP on cyclic AMP levels seems to be a more general phenomenon. But, the reverse hierarchy of the cyclic nucleotides is also found; at increased concentrations, morphine or naloxone cause a rise in the level of cyclic AMP whereas the cyclic GMP level is depressed (Figs 1 and 2). What is the molecular basis of these antagonisms? Most of the actions of cyclic nucleotides are mediated through the agency of protein kinase and phosphorylation reactions. Thus, it is interesting to note that such phosphorylation reactions have been shown to inhibit adenyl cyclase activities[18].

Besides antagonising the effect of morphine at concentrations below 0.1 μmol l^{-1} and increasing levels of cyclic AMP at concentrations above 10 μmol l^{-1}, naloxone causes a third effect. Although, alone at concentrations less than 10 μmol l^{-1} it does not depress the level of cyclic AMP below the control value, it does so in the presence of

10 μmol l^{-1} morphine (Fig. 2): that is, it overcompensates the stimulatory effect of morphine. Experiments are under way in an attempt to elucidate the mechanism of this unusual action.

The opposite actions of morphine or levorphanol at low and high concentrations suggest that these opiate effects are mediated by receptors of high and low opiate affinity, respectively. Since, at high concentrations levorphanol and dextrorphan have the same effects, the low affinity receptor should lack stereospecificity. High and low affinity opiate binding sites of high and low stereospecificity, respectively, have been detected in brain[19]. Opiates do not normally occur in animals. There should therefore exist in brain at least two different natural ligands of hormone-like character, which bind to the "opiate receptors" and which are mimicked probably by different parts of the opiate molecules. We like to suggest that the actions of these endogenous ligands should be mediated by cyclic GMP and cyclic AMP, respectively. We are trying to isolate and identify these substances.

We cannot yet decide whether in opiate action the increase in levels of cyclic GMP or the depression of (hormonally increased?) cyclic AMP levels by elevated levels of cyclic GMP is the key event. This is an important issue, since it has been proposed[12] that a mechanism, whereby morphine-like drugs exert their analgesic and other effects, is the inhibition of the stimulation by PGE₁ of cyclic AMP production. But morphine also inhibits the stimulation of cyclic AMP formation caused by other agents[7]. Thus, the antagonisms between PGE₁ and morphine may or may not be a fortuitous combination of little physiological significance.

2-Hydroxy-oestradiol-17β as a possible link in steroid brain interaction

IN spite of wide evidence for their existence, mechanisms of steroid–brain interaction are poorly understood. It has been reported that hydroxylation of oestrogens occurs in the liver[1,2] and that hydroxylated oestrogens such as 2-hydroxy-oestradiol-17β (2-OHE₂) are strong competitive

inhibitors of the methylation of catecholamines by catechol-O-methyltransferase[3]. We report for the first time the action of 2-OHE₂ on the brain. Our experiments demonstrate that 2-OHE₂ lowered plasma levels of the anterior pituitary luteinising hormone (LH). A response was recorded from the amygdala, which accumulate gonadal steroids[4,5] and participate in the regulation of the anterior pituitary.

Nine adult miniature pigs (Göttingen strain) were orchidectomised at least 4 weeks before the experiment, and kept in daylight and otherwise standard conditions. Stainless steel tubing (22 G) with inner exchangeable tubing (27 G) was stereotaxically and bilaterally implanted into the amygdala Histology showed that in seven animals the tip of the implant was located in the basolateral and cortico-medial amygdala and in two animals outside the amygdala. Two weeks after the implantation, a catheter was placed into the vena jugularis externa for the collection of blood samples. Treatment started 5 d later. Each individual unanaesthetised animal was microinjected by way of the inner cannula using a 10 μl Hamilton syringe (2 μl single injection; stock was made up from 7 ml 0.9% NaCl and 3 ml 20% ethanol (EtOH)). Several days later 2-OHE₂ (2 μl NaCl-EtOH containing very freshly dissolved 60 ng 2-OHE₂) was microinjected. This was followed by another NaCl-EtOH control treatment. Microinjections lasted no longer than 1–2 min. Blood samples (2 ml) were collected at 15 min intervals from each animal: nine samples 120–0 min before, eight 15–120 min and eight 135–240 min after the microinjection. At 24 and 48 h after injection, blood was collected again at 15 min intervals for 90 min. A 4-day recovery was allowed between treatments. Plasma LH was analysed by double-antibody radioimmunoassay[6]. In addition to the two control animals with implants just outside the amygdala, elaborate experiments were performed to exclude leakage to other brain regions, the pituitary or the peripheral circulation. These included application of radioactive steroids into rat and pig brains, estimations of the distance of diffusion, as well as radioimmunological determination of circulating steroid levels after steroid microinjections identical to those of 2-OHE₂ (N.P. and F.E., unpublished).

Table 1 shows that 2 μl NaCl-EtOH had no effect on plasma LH levels. 2-OHE₂ decreased plasma LH significantly at 13 out of 27 points of time. The number of animals with a significant decrease in plasma LH after injection increased with time. Microinjection of any substance outside the amygdala did not alter plasma LH significantly. An individual response during the entire experiment is shown in Fig. 1. The consistent changes in plasma LH after the microinjection of 2-OHE₂ into the amygdala clearly show that this compound can alter brain pituitary function. The well known fact that oestrogens concentrate in the amygdala[4,5] and observation that increased catecholamine content in the amygdala is associated with lowered plasma LH levels[7] are consistent with the mechanisms of action of

Table 1   Effect of microinjections of 2-hydroxy-oestradiol-17β (2-OHE₂) on plasma LH levels in orchidectomised adult miniature pigs

Time after microinjection (h)	NaCl-EtOH*		2-OHE₂ (60 ng–2 μl NaCl-EtOH)			NaCl-EtOH	
	n	NC	n	D	NC	n	NC
0–2	7	7	7	2	5	5	5
2–4	7	7	7	3	4	5	5
24–25.5	7	7	7	4	3	4	4
48–49.5	7	7	6	4	2	2	2

* 2 μl NaCl-EtOH (7 ml 0.9% NaCl + 3 ml 20% ethanol).
n, Number of animals. Two animals in which the tips of cannulas were outside the amygdala are not considered in the Table. They did not cause a change.
D, Decrease in plasma LH levels. Significant (at least $P < 0.05$, Student's t test) when compared with the control periods.
NC, no change.
Fig. 1 Plasma LH (mean±s.e.m.; LER-786-3) after micro-injection of 2-OHE₂ into the amygdala of an individual orchid-ectomised adult miniature pig. NaCl–EtOH: 2 μl of a stock made from 7 ml 0.9% NaCl and 3 ml 20% EtOH; 2-OHE₂: 2 μl NaCl–EtOH containing 60 ng OHE₂; number of samples per block: seven to nine, obtained at 15 min intervals. Each column (*b–e*) was compared with the corresponding control period (*a*) by Student's *t*- test. 2-OHE₂ treatment resulted in significant decrease in columns (*b*) and (*c*), ($P \leq 0.001$) and in column (*d*), ($P \leq 0.01$). *a*, 0–2 h before microinjection; *b*, 0–2 h after microinjection; *c*, 2–4 h after microinjection; *d*, 24–25.5 h after microinjection, *e*, 48–49.5 h after microinjection.

2-OHE₂ (ref. 3). It remains to be established whether it is crossing the blood–brain barrier or is synthesised in the brain, or both. It is also necessary to determine whether 2-OHE₂ actions occur in other oestrogen-concentrating brain areas.

2-Hydroxy-oestradiol-17β was kindly provided by Dr H. Breuer, Bonn, Germany, the LH antiserum by Dr G. D. Niswender, Fort Collins, USA and the LH standard by Dr L. E. Reichert, Atlanta, USA. This work was supported by the Deutsche Forschungsgemeinschaft.

Amino acid synthesis through biogenetic-type CO₂ fixation

In bacterial photosynthesis, reductive CO₂ fixation was thought to proceed through activation of carboxylic acid by coenzyme A followed by the reductive incorporation of CO₂ in the presence of reduced ferredoxin (a kind of non-haem iron–sulphur protein) and an enzyme, pyruvate synthase, as shown in equation (1). The reaction takes place *in vitro* in the same way using CoA, reduced ferredoxin and pyruvate synthase[1].

$$CH_3C{\sim}\textcircled{P} \longrightarrow CH_3C\text{-S-CoA} \xrightarrow[\substack{ferredoxin_{red.} \\ pyruvate\ synthase}]{CO_2} CH_3CCO_2H$$

(1)
During attempts to prepare some artificial photosynthetic models, we have discovered a similar biogenetic-type reaction which uses a simple catalyst modelling ferredoxin activity. As catalysts, we used some known iron–sulphur

complexes such as Schrauzer's complex[2], Yang's complex[3], and Holm's complex[4].

We now wish to report that completely artificial catalytic systems, one of which consisted of a simple alkyl mercaptan, one of the ferredoxin models, and an inorganic reductant, also carried out the reaction[1]. Moreover, the CO₂ fixation products, α-keto acids, were successfully converted to the corresponding α-amino acids on treatment with pyridoxamine. It is worth noting that all of these reactions can be carried out in one step as shown in equation (2).

$$RCH_2COH \longrightarrow RCH_2CSC_8H_{17} \xrightarrow[\substack{Schrauzer's\ complex \\ Na_2S_2O_4,\ NaHCO_3 \\ in\ THF\text{-}MeOH\text{-}H_2O}]{CO_2} \left(RCH_2CCO_2H\right)$$

$$\xrightarrow[\substack{pyridoxamine \\ zinc\ acetate}]{} RCH_2CHCO_2H$$
$$\overset{|}{NH_2}$$

(2)
Gaseous CO₂ was bubbled into a solution consisting of tetrahydrofuran (30 ml), methanol (15 ml), water (7.5 ml), synthetic iron–sulphur complex (500 mg, 9.2×10^{-4} mol), sodium hydrosulphite (10 g. 6×10^{-2} mol) and sodium bicarbonate (500 mg, 6×10^{-3} mol). The solution turned dark green, presumably as a result of the formation of the reduced iron–sulphur complex soluble in the solvent. Now, *n*-octyl thiolphenylacetate $C_6H_5CH_2COSC_8H_{17}$ (264 mg, (10^{-3} mol), pyridoxamine dihydrochloride (48.3 mg, 2×10^{-4} mol), potassium hydroxide (22.4 mg, 4×10^{-4} mol) and zinc acetate (55 mg, 2.5×10^{-4} mol) were added to the solution. CO₂ bubbling was continued under efficient reflux and with stirring at room temperature. After 9 h bubbling, the reaction mixture was extracted three times with ether. The aqueous solution was subjected to anion exchange resin chromatography using quarternary ammonium resin.

The products were absorbed on the resin, and eluted with aqueous HCl. The product appeared in the first 1 N-HCl elute, and behaved as authentic phenylalanine, giving a thin-layer chromatography (TLC) spot (silica gel) of the same R_f value with phenylalanine and the same red-purple colour as phenylalanine when treated with ninhydrin. On treatment with CH₂N₂, products gave the same TLC R_f value (silica gel) and red-purple colour as the methyl ester of phenylalanine, and also the same retention time on gas chromatography. Phenylalanine formation in the present reaction was confirmed through coinjection with authentic methyl ester of phenylalanine, infrared and mass spectroscopy.

Thus, the synthesis of phenylalanine by CO₂ fixation with completely artificial (non-enzymatic) catalysts was achieved without addition of any subcellular material. The formation of phenylpyruvic acid was also fully confirmed as phenyl-hydrazone (TLC, infrared spectroscopy and nuclear magnetic resonance) and its methyl ester (TLC). This strongly indicates that phenylalanine was formed from phenylacetic acid (or more favourably from its thiol ester) by way of phenylpyruvic acid (as a reductive CO₂ fixation product) by amino transfer from pyridoxamine as shown in equation (2).

Alanine and leucine were similarly synthesised from corresponding thiol esters of carboxylic acids; the structures of amino acids thus formed were ascertained by TLC and vapour phase chromatography (VPC) after converting them into the appropriate derivatives.

Control experiments were carried out where each of the important components in turn was omitted from the complete system which consists of thiol ester of phenylacetic acid, Schrauzer's complex, sodium hydrosulphite, CO₂ gas,

and amino transfer reagents—pyridoxamine dihydrochloride, potassium hydroxide and zinc acetate. In these control experiments, no trace of phenylalanine was detected. These results show that all of the important components are necessary for the synthesis of an α-amino acid.

The possibility of contamination especially with α-amino acid and/or α-keto acid in all reagents used (whether prepared by us or not) was excluded.

The iron–sulphur complex used in the present non-enzymatic system involves the so-called "Schrauzer's complex," first synthesised by G. N. Schrauzer and its structure in the oxidised state is shown in equation (3).
Schrauzer's complex

(3)

The complex showed the same melting point and characteristic infrared spectrum as reported[2]. The insoluble complex was easily reduced with sodium hydrosulphite and the reduced form was soluble in the present solvent. The reduced form has λ_{max} at 314 and 443 nm.

The electronic spectra of Yang's complex[3]. Holm's complex[4] and cysteine-containing peptides[5] were shown to be very similar to those of ferredoxin, and characteristics of reduced iron–sulphur proteins such as their ENDOR and ESR spectra[8], magnetic susceptibility[6] and redox potential[4] were approximately reproduced by artificial iron–sulphur complexes. Our success in a fully artificial CO_2 fixation using Schrauzer's complex may be caused by the similarity of electronic structure between artificial iron–sulphur compound and iron–sulphur protein.

The present non-enzymatic reaction is novel and will aid understanding of the chemical nature of the biological CO_2 fixation process. It is true that this non-enzymatic reaction gives only a low yield, but it is still close to the yield of *in vitro* enzymatic CO_2 fixation. The yield of pyruvic acid was 0.66% based on acetyl phosphate used. The yield in the present reaction was 0.3% based on pyridoxamine used. Some attempts to improve the yield of non-enzymatic CO_2 fixation are now in progress.

Seasonal rhythm in plasma testosterone and luteinising hormone of the male laboratory rat

SEASONAL reproductive rhythms of animals living in natural conditions[1–4] as well as domestic animals[5,6] have been the subject of extensive research. Seasonal rhythms in experimental laboratory animals living in a constant laboratory environment, however, have been considered improbable. The first report on seasonal rhythms in laboratory animals was made in 1958 by Gunn and Gould[7], who reported a seasonal cycle in the uptake of ^{65}Zn by the dorsolateral prostate of the male rat, with elevations in February–March and June–July. Comments on the possibility of seasonality of androgenic hormones[8,9] only emphasise that no study has been reported on the male laboratory rat to determine whether there are seasonal variations in plasma testosterone and luteinising hormone (LH) throughout the year. We began such a study in January 1973 and report data collected up to June 1974, which suggest a circannual rhythm in sex hormones in male laboratory rats living in what is apparently a constant environment.

At the time the study began, eight rats of Sprague–Dawley descent were placed in a windowless vivarium with lights on from 0600 to 1800 (eastern standard time). Temperature was maintained at 21 ± 1 °C; Purina rat chow and water were provided *ad libitum*. The animals lived in the experimental environment for 4 weeks before the first blood was collected on February 15, 1973, when the rats were 85 d old. Approximately 1 ml of blood was collected monthly by cardiac puncture under ether anaesthesia. Blood was collected between 1000 and 1200. Other rats of similar birthdate and treatment were added to the study during the first nine months to replace animals lost while collecting blood. On November 1, 1973, animals more than four months old were added to replenish the experimental group, which was badly depleted due to loss of ageing animals. Plasma testosterone and LH levels were also measured in a control group (age control) of six 90-d-old and six 100-d-old males during the spring of 1974, to evaluate the effect of age on seasonal changes in hormone levels. Testosterone concentration was measured by radioimmunoassay using a method we developed[10], LH concentration by an ovine-ovine rat radioimmunoassay[11].

In the 18-month study of rats more than 80 d old, plasma testosterone concentration showed a significant elevation in February–March, 1973 (designated the spring surge) (Fig. 1). There was no spring surge, however, in 1974 in animals more than 180 d old, although plasma testosterone levels were elevated in the younger rats (age control) (Fig. 1). LH levels also rose significantly in the spring of 1973, but did not rise in older male rats in the spring of 1974 (Fig. 1), although the concentration of LH was elevated in the age control group.

The rise in plasma testosterone in 85-d-old rats during February 1973 and 130-d-old rats during March 1973 in our 18-month study contrasted with a report by Grota[12], who described a testosterone surge in 60-d-old rats after which the hormone decreased sharply as the animals aged. Since Grota did not report the birthdate of his experimental animals, we repeated his study in males born in the spring (April 22, 1974) and autumn (October 15, 1973).

In rats which matured in the summer, plasma testosterone levels increased at 61 d of age (June 22) and then decreased (Fig. 2), as Grota reported. In animals born in the autumn, however, plasma testosterone levels increased at 50 d of age, decreased at 60 d, and then increased sharply at 90–100 d (Fig. 2), during January 1974. Apparently the seasonal surge which we observed in our original experiment was based on the fact that in rats born in the autumn, the 60-d plasma testosterone surge was delayed until spring.

The thesis that the 60-d plasma testosterone surge is subject to seasonal regulation was tested further by examining plasma testosterone levels in successive groups of rats, reaching 60–65 d of age during each month of the year except April. A 60-d surge was noted in all months but June and December (Fig. 3), if we define a surge as >3 ng ml^{-1}. Although the relatively low levels of plasma
Fig. 1 Plasma testosterone (lower) and LH (upper) concentrations of mature male rats (>85 d of age) over 18 months. Each point in the figure represents ng ml^{-1}, mean±s.e.; the number of animals tested is given in parentheses above each point. Rats were purchased from Russell Miller Farms, at 50 d of age, and reared in vivaria under constant conditions, as described in the text. Blood was collected by cardiac puncture between 1000h and 1200h under light ether anaesthesia. Testosterone and LH were measured by radioimmunoassay[10,11]. Statistical analysis (ANOVA and Student–Neuman–Keuls test) showed that plasma testosterone was significantly increased ($P<0.05$) during February and March 1973 over all other sampling times. Plasma LH was significantly increased ($P<0.05$) during March 1973 over all other sampling times. In the age control group of 90-d-old and 100-d-old animals tested during January 1974, hormone levels were significantly increased ($P<0.05$) compared with other sampling periods of older animals during 1974.

testosterone of 60-d-old rats in June did not represent a delay but rather a diminution of the 60-d surge (Fig. 2), the low levels of plasma testosterone of 60-d-old male rats in December did represent a delay in the surge, which reached a maximum in January 1974, when the rats were 90–100 d old (Fig. 2).

Rats older than 5 months did not respond in the spring, but instead their previous 60-d surge showed increasingly higher levels of plasma testosterone depending on their date of birth (compare Fig. 3, July to November). We investigated whether older rats could respond to gonadotrophins by injecting 0.1 IU human chorionic gonadotropin (HCG) per 100 g body weight into 8-month-old male rats and comparing their plasma testosterone levels over 2-h with those of HCG-injected 3-month-old rats (Table 1). Although we found testosterone concentrations consistently lower in aged rats, both groups responded significantly to HCG stimulation.

Apparently the hormonal seasonal surge was not based on testicular competence but reflected a complex regulation which is not solely dependent on environmental cues. The delay in the 60-d surge of animals born in the autumn is reminiscent of delayed sexual maturation of the field rodent during the winter[13]; in fact we recently observed a stunting of body weight during the growth of autumn-born animals

during the winter. It could be argued that the vivarium's "constant environment" contained hidden cues (in part-
Fig. 2 Plasma testosterone concentrations of maturing male rats in summer (O) (born April 22), and in winter (●) (born October 15). Each point represents the ng ml^{-1}, mean ±s.e. of six animals. Animals were purchased from Russell Miller Farms at 21 d of age and maintained in our vivaria in constant conditions as described in the text.

Table 1 Effect of HCG on plasma testosterone levels of young and old male rats

Group	Treatment	Control sample	Time (min) after injection 15	30	60	120
Young	Saline	1.17±0.34	1.33±0.31	1.47±0.42	1.66±0.42	2.11±0.37
Young	HCG	1.01±0.07	1.85±0.29	3.42±0.38	5.48±0.75	6.96±0.91
Old	Saline	0.85±0.17	0.95±0.13	0.89±0.13	0.72±0.15	0.86±0.22
Old	HCG	0.65±0.15	0.92±0.08	2.04±0.42	3.78±0.44	5.79±0.71

Figures are ng ml^{-1}, mean ±s.e. three-month and 8-month-old male rats were cannulated with PE-50 tubing in the right external jugular vein 24 h before initiation of the experiment. 0.25 ml of blood was collected 3-10 min before treatment (control sample). 0.1 IU of HCG per 100 g body weight or an equivalent volume of physiological saline was then injected into the cannula which was rinsed with 0.2 ml of saline. Blood (0.25 ml) was collected 15, 30, 60 and 120 min after injection. Analysis of variance showed a significant increase ($P<0.005$) in plasma testosterone levels after the injection of HCG. There was no difference in responses between young and old rats. The experiment was run between 1230 and 1600 during August 1974. Animals were purchased from Russell Miller Farms 30 d before the experiment began and maintained in our vivaria in constant conditions as described in the text.
Fig. 3 Comparison of plasma testosterone levels of mature (solid bar) and 60-d-old to 65-d-old (open bar) male rats in different months of the year. The number of animals tested is within the parentheses above each bar. Mean values are graphed; s.e. is included for young animals only. Data of mature rats are from Fig. 1. Rats were bred in our vivaria from the same stock as described in Fig. 1, and reared in constant conditions as described in the text. Analysis of variance showed a significant difference between ages ($P < 0.01$), among months ($P < 0.025$) and a significant age by month interaction ($P < 0.01$).

icular, seasonal fluctuations of plant oestrogens in animal food). It is difficult to sustain this thesis. First, we obtained similar results over several years, using both home-bred and commercially-bred animals which grew up in different environments with different food; second, animals of different birth dates and ages but living in the same evironment responded differently to seasonal influences; third, close examination of two recent reports[14,15] indicates that female rats are also seasonally regulated; and fourth, our animal food purchases and storage were unscheduled.

This report provides the first experimental backing to a growing realisation among scientists that experimental results may differ, depending on the season of the year, particularly when hormonal events with circadian rhythmicity are being examined[16]. While the concept that seasonality may be based on internal factors and not on changing environmental conditions is difficult to accept, it now has experimental as well as ideological support[17,18].

Our research was supported in part by grants from the NIH. We thank the following for donation of materials used in radioimmunoassays: Dr B. V. Caldwell, Dr G. D. Niswender, Dr L. E. Reichert, Jr, and the NIH.

An approach to amino acid sequence analysis of transplantation antigens

THE major histocompatibility complex of the mouse, known as the H-2 locus, represents the prime barrier against successful tissue transplants[1] and controls the expression of many cell surface alloantigens which are serologically detectable[2,3]. It may be subdivided by recombinational analysis into four major regions known as K, D, Ir and Ss (ref. 4). The Ss region controls the quantitative expression of a serum protein[5]. The Ir region controls immune responsiveness of mice to a variety of synthetic and natural antigens[6,7], and the expression of multiple cell surface proteins, some of which may be distinguished by molecular weight[8,9]. The K and D regions both control the expression of distinct cell surface glycoproteins (molecular weight 47,000), which are non-covalently associated with a small molecular weight (11,500) component[10-11]. Because the native molecules are hydrophobic proteins present on the cell surfaces in small quantities, it is necessary to use unusual procedures for their isolation and chemical characterisation. We have, therefore, used indirect immunoprecipitation and sodium dodecyl sulphate (SDS) polyacrylamide gel electrophoresis (PAGE) for the isolation and subsequent amino acid sequence analysis of both molecular weight components.

Cell surface proteins of B10.D2 spleen lymphocytes were

Fig. 1 Preparations of the small molecular weight component which had been intrinsically radiolabelled with ^{3}H-tyrosine ($\triangle$) or ^{3}H-lysine ($\bullet$) were combined and analysed on an automated sequenator. The PTH–amino acid derivative from each cycle was combined with an appropriate mixture of unlabelled PTH–amino acids and separated by one dimensional thin layer chromatography on silica gel plates (Eastman–Kodak) using benzene–acetic acid (9:1) as the chromatographic solvent. PTH–amino acid spots were visualised by short-wave ultraviolet light, excised from the plate, and counted in a liquid scintillation counter. The amount of radioactivity associated with each of the PTH–amino acids is plotted against the step number.
Table 1 Amino acid sequences of B_2-microglobulin

	1	2	3	4	5	6	7	8	9	10

Rabbit	Val	Gln	Arg	Ala	Pro	Asn	Val	Gln	Val	Tyr
H-2 associated polypeptide	—	—	Lys	—	—	—	—	—	—	Tyr

radiolabelled by incorporation of single tritiated amino acids. The H-2.4 alloantigen (product of the H-2D region) and its associated polypeptide were isolated by indirect immunoprecipitation using specific H-2 alloantiserum, and purified on SDS PAGE gels as described previously[11]. Each molecule was eluted from the gel by overnight incubation of appropriate gel slices in 0.01% SDS. When re-electrophoresed on SDS gels, the eluted material migrated as a single molecular weight peak. Before sequence analysis, each sample was dialysed twice against 0 001% SDS. Sequential protein degradation was performed on a Beckman Model 890 sequencer using the procedure of Hermodson[12]. Radioactive phenylthiohydantoin (PTH) derivatives were analysed by thin-layer chromatography as described in Fig. 1.

Sequence analysis of the small molecular weight component enabled the assignment of lysine and tyrosine as the amino acid residues to positions 3 and 10 respectively (Fig. 1). A comparison of our sequence assignment with the amino acid sequence of human[14], rabbit[15] and dog[16] B_2-microglobulin isolated from urine (Table 1) supports our previous suggestion[11] that the H-2 associated polypeptide is analogous to the B_2-microglobulin-like molecule found associated with detergent solubilised HL-A alloantigens[13]. Recent preliminary data from our laboratory have enabled us to identify valine as the amino acid residue at position 9 in the small molecular weight component. In addition, rat B_2-microglobulin has been shown by other investigators to have a lysine residue at position 3 (ref. 17). Both findings further support this suggestion.

Amino acid sequence analysis of the H-2.4 alloantigen by this procedure enabled the assignment of leucine and tyrosine residues to position 5 and 7 respectively (Fig. 2). The observed low experimental yield (approximately 40% of theoretical) is probably caused by protein 'washout' from the sequenator cup, and loss of exchangeable tritium.
Nevertheless our data suggest that the sequence obtained is representative of a major component of the purified material, and that the H-2.4 alloantigen does not have a blocked N terminus.

These sequence data were obtained from protein which had been isolated from two mouse spleens or approximately 0.15 nmol protein, 1/1,000 the amount normally required for automated sequence analysis. Our results suggest that the H-2 alloantigens as well as other membrane proteins may be amenable to this type of sequence analysis.

Determination of the chemical structure of H-2 and other histocompatibility alloantigens as well as the elucidation of the chemical basis of their antigenicity has implications for tissue and organ transplantation. For example, use of such knowledge may make it possible to render prospective organ recipients specifically tolerant to the unique histocompatibility alloantigens of the prospective donor. In addition, further chemical analysis may clarify the function of the histocompatibility alloantigens and contribute to our basic understanding of cell membrane proteins.

Stable large variant of 5S RNA in Clostridium thermosaccharolyticum

THE precursor forms of prokaryote 16S and 23S ribosomal RNA (rRNA) are larger than their mature counterparts by some 10% (refs 1–5). An analogous large precursor form of the bacterial 5S RNA exists (in at least some cases)[1,3,6,7]. The reason for the existence of these rRNA precursor forms is not known. They could merely reflect an aspect of the transcription process, or they could have evolved specifically to facilitate ribosome assembly. A more intriguing possibility is that they represent vestiges of ancestral rRNAs, retained because they are essential to ribosome assembly—which process must reasonably recapitulate, to some extent, ribosomal evolution. This last alternative gains some support from our

discovery of a stable form of the 5S RNA some 30–40% larger than normal, in *Clostridium thermosaccharolyticum*.

Polyacrylamide gel profiles of ^{32}P-labelled RNA from *C. thermosaccharolyticum* exhibit an extra band that corresponds to an RNA species of about 160 nucleotides. The new species plus the normal 5S RNA together exist in approximate unit mole ratio to the 16S and 23S rRNAs. The new species is indeed RNA and stable because a high specific activity pulse of ^{3}H-uridine (>90% incorporated in less than one cell generation) is incorporated into it; and the ratio of ^{3}H in the new RNA species to that in 5S RNA remains constant (about unity) for at least four generations (the length of the experiment).

Figure 1 is a polyacrylamide gel profile of RNA extracted from the 50S subunit. Both normal 5S RNA and the new RNA species are found on this subunit. Although all this evidence may suggest the new RNA species to be of the 5S RNA genre, definitive proof depends on some more detailed characterisation, such as oligonucleotide fingerprinting.

Figure 2 shows tracings of the two-dimensional electro-phoretograms of T1 ribonuclease digests of both the normal 5S RNA (form I) and the new species (form II) from *C. thermo-saccharolyticum*. Table 1 catalogues the oligomers found in both T1 and pancreatic ribonuclease digest of the two forms.

Form II contains (almost) every oligonucleotide found in form I. We conclude, therefore, that form II is a '5S' RNA. Form II also has an additional forty or so nucleotides not found in form I, giving the former an approximate size of 160 nucleotides. Both forms contain the same 5' hexanucleotide, pUUUCCG. The 3' terminal oligonucleotide of the shorter form I, however, is absent in form II. The simplest interpretation of this is that the excess material unique to form II occurs as an extension of the 3' terminus of the normal molecule. The presence of several potential stable base-pairing sequences—GGGGU to [C$_{4-5}$U]G and ACUUUUUUG to GAAAAGU—predicts that the excess material in form II will possess considerable secondary structure.
Fig. 1 Polyacrylamide gel electrophoretic profile of RNA from 50S subunit of *C. thermosaccharolyticum*, grown anaerobically in 5 ml dephosphorylated yeast extract–peptone medium to which Na$_2$S and cysteine were added[8]. Approximately 100 µCi of [32]PO$_4$ were added to the culture early in log phase and the culture collected three to four generations later, by low speed centrifugation (12,000g for about 10 min). Cells were ruptured by passage through a French press, and the lysate, cleared of all debris—again by low speed centrifugation—was layered on a 5–20% sucrose gradient in a 10 mM Tris buffer, pH 7.4, containing 0.1 mM MgCl$_2$. After centrifugation (90,000g for 9 h in a Spinco SW 25.1 rotor), the resulting 50S peak was collected, dialysed to remove sucrose, and the RNA extracted by the phenol method[9], the purified RNA being subsequently analysed by polyacrylamide gel electrophoresis. A split gel method was used[10], the initial portion comprising 3.2% acrylamide (a), the final portion, 10% acrylamide (b). The large peak in the 3.2% gel section has the mobility one would expect for 23S rRNA; the peaks labelled I and II in the 10% section of the gel have the mobilities expected for normal 5S RNA and the new RNA species, respectively. The remaining material in the 10% section of the gel is presumably tRNA and/or 23S rRNA breakdown products.

Oligomer spots shown in Fig. 2 and comparable spots from pancreatic nuclease fingerprints were sequenced as described previously[12-14]. Where order is uncertain in an oligomer, the nucleotides in question are in parentheses. Quantification by scintillation counting of excised spots in a non-aqueous scintillant (BBOT) are given to the nearest 0.5 mol ratio.
*Identification not certain.

A possible explanation for form II is that it is related, at least in an evolutionary sense, to 5S precursor forms[6,7]. Sogin and Pace have shown that the conversion from precursor to

mature 5S RNA (in Bacilli) involves cleavage by the same enzyme at points defining both the 5' and 3' termini of the mature 5S RNA (ref. 7). An identical large purine stretch is found about 20 nucleotides proximal to the point of cleavage in each instance, and presumably therefore, serves as a recognition signal for the enzyme, RNase m5 (ref. 7). Were this the general mechanism for 5S RNA maturation (in prokaryotes), it would demand in the present case that form II not contain such a signal defining a normal 3'-terminal cleavage point. Indeed, form II does not possess one large purine stretch, GGAAGU, found in form I, but its position in the molecule is unknown at present.

The existence of a large form of the 5S RNA raises many questions regarding both function and evolution in the ribosome. The trivial explanation that the large form of 5S RNA has neither functional nor evolutionary significance cannot be ruled out, but it seems unlikely. Ratios of the two forms of 5S RNA from cells grown at the extremes of the organisms' growth range (that is, 45 and 65 °C) are not significantly different, ruling out the possibility that one form may be used preferentially at higher growth temperatures. We have not determined whether this ratio varies during sporulation.

As yet, the stable large form of 5S RNA is unique to *C. thermosaccharolyticum*. It is definitely not present in Bacilli[6,7], and we have looked for, but failed to find it in mesophilic Clostridia, even in representatives of the same subgroup classification as *C. thermosaccharolyticum* (K. Luehrsen and C.W., unpublished).

Two explanations remain. It could be a retention of or return to an ancestral type of 5S RNA—the latter being made possible through retention of ancestral characteristics in precursor forms of the 5S molecule. On the other hand, it may represent a novel evolutionary happening, having no resemblance to archaic forms of 5S RNA. We do not favour the latter on the grounds that the change in passing from the normal to enlarged form of 5S RNA is a drastic one (and would probably require further evolutionary changes in the ribosome), and it would seem *a priori* unlikely to occur in a fully evolved ribosome (that is, in one species of one genus).

Fig. 2 Tracings of two-dimensional electrophoretograms of T1 ribonuclease digests of 5S RNA (form I) and the new RNA species (form II). *C. thermosaccharolyticum* was grown, labelled, and cells ruptured as described in Fig. 1, except that 5-10 mCi $^{32}PO_4$ were added to the culture. Cell lysate was extracted immediately by the phenol method[9], and the resulting RNAs isolated by electrophoresis on 10% polyacrylamide gels. Appropriate RNA bands were located by radioautography of the intact gel, the bands cut out, and the RNA extracted by phenol[11]. Specific activities of the RNA varied from preparation to preparation, but were within the range 0.5–2 µCi per µg RNA. The two RNAs were purified by passage over BD-cellulose[10], digested with T1 ribonuclease and the resulting products analysed by a modification of two-dimensional electrophoretic method[12-14]. The first electrophoretic dimension was run on cellulose acetate at *p*H 3.5, the second on DEAE-cellulose paper in a 0.1 M pyridine solution brought to *p*H 2.3 with formic acid (ref. 14 and M. Sogin, D. Stahl, L. Bonen and C.W., unpublished). Oligonucleotides unique to Form II are italicised.

Oxygen binding to haemoglobins of the primitive vertebrate *Myxine glutinosa* L.

THE Atlantic hagfish (*Myxine glutinosa* L.) belongs to the family Myxinidiae which forms along with the family Petromyzonidae (the lampreys) the only living class of jaw-

less vertebrates (Agnatha), the Cyclostomata. These Cyclostomata are considered on morphological[1] and physiological[2,4] evidence to be the most primitive form of living vertebrates and are distant descendants of fossil forms of Agnatha which were already present during the Ordovician, that is, more than 400 Myr ago[1,3].

The oxygen-binding characteristics of hagfish haemoglobin offer an opportunity to obtain information on the evolution of the respiratory function of haemoglobin. It seems[4-10] that hagfish haemoglobin, unlike all known haemoglobins of higher vertebrates which carry four haems per molecule, has only one oxygen-binding site. Not unexpectedly they exhibit little, if any, allosteric effects, such as cooperativity of oxygen binding and Bohr effect, and would be therefore called 'primitive' in comparison to more advanced forms of molecular organisation of respiratory proteins represented by tetrameric haemoglobin. If the oxygen-binding characteristics of the haemoglobins of *M. glutinosa* reported here, however, are compared with those of the Pacific[5,6] (*Eptatretus stoutii*) and Japanese[7] (*E. burgeri*) hagfish, it seems that these groups of animals form distinct functional entities and can be called 'primitive' only from a comparative point of view.

Preparation of haemoglobin solutions from the blood of *M. glutinosa* and fractionation of the three major components (Hb$_I$, Hb$_{II}$, Hb$_{III}$) was carried out as described previously[9,10]. We found that the three major types of haemoglobin which are present in the blood of *M. glutinosa* have different oxygen affinities (Fig. 1), but did not show any sign of cooperativity when judged from the exponent n in the Hill equation[13]. Even though Hb$_I$, Hb$_{II}$ and Hb$_{III}$ represent only 52% of the total (the remainder being minor components) they seem to govern the oxygen affinity of the total haemolysate. This can be deduced from the good agreement between the partial pressure of oxygen at which haemoglobin is half saturated with oxygen (P_{50}) measured in the total haemolysate (4.2 mmHg at pH 7.3 and 20 °C) and that calculated from the respective percentage of each component[9] (4.3 mmHg in identical conditions). Hb$_{II}$ and Hb$_{III}$ did not change oxygen affinity in the pH range between 6.85 and 8.20, that is, they did not exhibit the Bohr effect. Note that multiple haemoglobin fractions of *E. burgeri* also showed functional heterogeneiety[7] although the major compounds A, B and C found in *E. stoutii* did not[6]. Thus, there is haemoglobin polymorphism in all three species of hagfish but in only two of them do different molecules

Fig. 2 Plot of log P_{50} against pH of hagfish haemolysate. O, Without CO_2; ●, in presence of CO_2. Note that in these latter experiments pH was changed by varying P_{CO_2} at constant $(23.9 \times 10^{-3}$ M l^{-1}) bicarbonate concentration. Upper part of figure shows the exponent n of the Hill equation[13] in which the lines represent the means obtained in the absence and presence (dotted line) of CO_2. Temperature was 20 °C and haemoglobin concentration 0.1×10^{-3} M l^{-1}. Buffers were 50 mM bis-Tris–100 mM NaCl in the absence of CO_2 and bicarbonate–NaCl buffer with a molarity of 150 mEq l^{-1} in the presence of CO_2. As methaemoglobin was present in some preparations, the samples were reduced with sodium dithionite and the reaction products removed on a mixed-bed ion-exchange column[11] before oxygen-binding experiments[12].

Fig. 1 Plot of log $(y/1-y)$ against log P_{O_2} for the isolated haemoglobins Hb$_I$ (O), Hb$_{II}$ (△), Hb$_{III}$ (□) of hagfish blood (Hill plot[13]). Y represents saturation of haemoglobin with oyxgen. P_{50}: 3.7, 2.3 and 6.3 mmHg for Hb$_I$, Hb$_{II}$ and Hb$_{III}$ respectively. Hill's exponent n averaged 1.03 for the three components. Temperature was 20 °C, pH 7.3 and haemoglobin concentration 0.1×10^{-3} M l^{-1}.

have different oxygen affinities. In particular environmental conditions such differences in haemoglobin function could be of physiological significance. If, for example, ambient temperature is raised, an increased synthesis of Hb$_{II}$ which has a high oxygen affinity (Fig. 1) would counteract the impaired oxygen uptake of the animal brought about by the high heat of oxygenation (-12.7 calorie mol^{-1}) which we determined in the haemolysate of *M. glutinosa*.

Consider the oxygen-binding properties of the whole haemolysate (Fig. 2). In the pH range of physiological importance for hagfish[4,5] (7.5–7.8) there was very little change in oxygen affinity with varying pH (Δlog P_{50}/ΔpH = -0.07) at least in the absence of CO_2, thus confirming the results of Manwell[4]. At pH less than 6.5 we observed a more pronounced Bohr effect which is, however, of no significance for the gas exchange in *M. glutinosa*. Addition of CO_2, on the other hand, significantly decreased oxygen affinity and increased the Bohr effect to -0.17 (Δlog P_{50}/ΔpH) in the range between pH 7.3 and 8.2. This relatively important increase in Bohr effect in the presence of CO_2 is still small in absolute terms and therefore compatible with the notion that fish living in an environment with varying CO_2 pressures (as the burrowing hagfish probably does), have in general a reduced Bohr effect[4,8]. Furthermore, the Hill parameter n increased significantly ($0.02 > P > 0.01$) on addition of CO_2, indicating that cooperativity of oxygen binding increased. This is probably caused by an increased tendency of the various components of *M. glutinosa* haemoglobin to aggregate. Such aggregation, also found in *E. burgeri*[7] and *Petromyzon marinus*[14,15] at low pH and high haemoglobin concentration, may be interpreted as an early attempt of nature to form the cooperative heterotetramers[16], which carry oxygen in the blood of higher vertebrates. In the isolated components Hb$_I$, Hb$_{II}$ and Hb$_{III}$ this specific effect of CO_2 on the oxygen-binding properties was not observed. Hb$_I$ and Hb$_{II}$ have blocked N-terminal amino groups, whereas in Hb$_{III}$ the N terminus is free to form carbamino compounds. This binding of CO_2 to Hb$_{III}$ does not seem to lead to self-aggregation which reflects itself in decreased oxygen affinity.

The question arises therefore how the CO_2 effect can be

explained. If it is not mediated by Hb_{III} there must be one or several minor components whose oxygen affinity is considerably decreased by CO_2. As the haemolysate of *M. glutinosa* contains more than ten of these minor fractions[9,10], none of which has been structurally characterised, it is impossible at present to identify the ones which may indicate the CO_2 effect. Nevertheless, the possibility should be kept in mind that the decrease in oxygen affinity produced by CO_2 could be brought about by interactions between different haemoglobin molecules. Such intermolecular interactions have a significant influence on the oxygen binding properties in the haemolysate of *E. burgeri*, even though the isolated, homogeneous components show practically no tendency to associate[7]. By the same token, it seems possible that the increased surface charge at specific sites in Hb_{III} (or some minor fractions), which is the result of carbamate formation, leads to an aggregate product between different molecules with a consecutive decrease in oxygen affinity of the whole haemolysate. In contrast to CO_2, other effector molecules which have large effects in tetrameric haemoglobin, like 2,3-diphosphoglycerate, inositol hexaphosphate and high concentrations of NaCl had no influence on oxygen affinity and cooperativity of *M. glutinosa* haemoglobin. Even an increase in protein concentration by a factor of six had no effect on P_{50} or the exponent n, in contrast to what is found in *E. burgeri*[7].

If we compare the P_{50} values which have been obtained in different species of hagfish in nearly identical conditions with respect to haemoglobin concentration, pH and temperature, *E. burgeri* has the lowest oxygen affinity $(P_{50} = 10\ mmHg)[7]$ being followed by *M. glutinosa* $(P_{50} = 4.2\ mmHg)$ *E. stoutii* has the highest oxygen affinity $(P_{50} = 1.6\ mmHg)[5,6]$. As long as we know as little as we do on ambient conditions and the respiratory capacity of these animals it would be inappropriate to draw any far reaching conclusion on possible ecological advantages of such differences in oxygen-binding characteristics of hagfish haemoglobin. These particular respiratory proteins seem to be primitive in the sense that they exhibit very limited allosteric effects. Note, however, that hagfish are biologically very successful animals so that their haemoglobins are likely to fulfil their physiological function quite well. Oxygen exchange, for example, takes place at such low internal partial pressures of oxygen in these animals[4] that the absence of significant cooperativity of oxygen binding to haemoglobin does not seem to have any adverse effects on oxygen delivery to the tissues.

Role of light and rhodopsin phosphorylation in control of permeability of retinal rod outer segment disks to Ca^{2+}

It has recently been shown in several laboratories that if isolated rod outer segments (ROS) are incubated in the presence of MgATP, rhodopsin is phosphorylated (see ref. 1). The reaction is much faster after the ROS have been exposed to light as the enzyme, 'opsin kinase', is specific to bleached rather than unbleached rhodopsin[1]. It has been suggested that the function of rhodopsin phosphorylation may be to regulate the responsiveness of ROS to light and in this paper we describe a mechanism whereby such a regulation could occur.

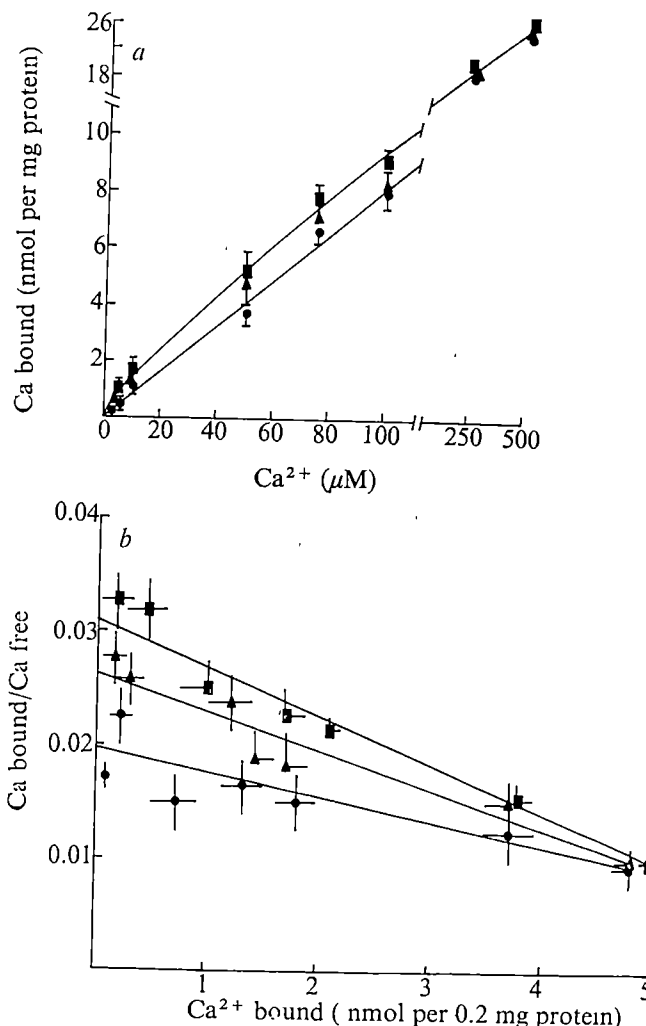
It is well established that the absorption of photons by


Fig. 1 Effect of Ca^{2+} concentration on the binding to ROS disks. Freshly prepared ROS were either kept in dim red light (●), exposed to white light for 2 min (▲), or exposed to white light for 2 min and phosphorylated at 37 °C at a protein concentration of about 0 5 mg ml^{-1} in 50 mM Tris-HCl, pH 7.4, and 1 mM MgATP for 30 min[1] (■). All samples were then washed by centrifugation from 10 mM Tris-HCl, pH 7.4, and incubated in dim red light at 37 °C at a protein concentration of about 0.2 mg ml^{-1} in 1 ml aliquots of 10 mM Tris-HCl, pH 7.4, and the stated concentration of $^{45}CaCl_2$ (specific radioactivity about 2×10^7 c p.m. μmol^{-1}) for 2 h to reach equilibrium (Fig. 3). Samples were then filtered using wet Millipore cellulose ester filters (0.45 μm pore size) and the filters washed with three 5 ml aliquots of 10 mM Tris-HCl, pH 7.4, placed in scintillation vials, and dried at 80 °C before adding scintillation fluid and counting. The washing procedure took less than 2 min and less than 2% of protein passed through the filters. Results are taken from five experiments and are shown as means ± s.d.

Fig. 2 Effect of exposure to light and phosphorylation on the rate of loss of Ca^{2+} from ROS disks. Freshly prepared ROS were either kept in dim red light (●), exposed to white light (▲), or exposed to white light and phosphorylated (■), and all samples washed with 10 mM Tris-HCl as described in Fig. 1. Samples were then incubated with 10 μM $^{45}CaCl_2$ (specific radioactivity 2×10^7 c.p.m. μmol^{-1}) in 0.3 M sucrose and 10 mM Tris-HCl, pH 7.4, at a protein concentration of about 0.3 mg ml^{-1} for 2 h and aliquots taken to determine the concentration of bound $^{45}Ca^{2+}$. The remaining material was centrifuged at 10^5g for 15 min and the pellets suspended in 10 mM Tris-HCl, pH 7.4, containing 0.3 M sucrose at a protein concentration of about 0.3 mg ml^{-1}. Samples (0.5 ml) were then taken at stated times and filtered through Millipore filters to determine the amount of $^{45}Ca^{2+}$ bound as described in Fig. 1. The time between the start of resuspension of the loaded pellets and the taking of the first sample was always 3 min. Results are taken from six experiments and show means ± s.d. The concentration of bound $^{45}Ca^{2+}$ at the end of the incubation with $^{45}CaCl_2$ was 1.78 ± 0.16, 1.90 ± 0.1 and 1.93 ± 0.1 nmol, $^{45}Ca^{2+}$ per mg protein for dark-kept, light-exposed, and light-exposed phosphorylated material, respectively.

vertebrate rods causes a hyperpolarisation which is thought to be the result of a decrease in Na^+ permeability of the ROS (refs 2–4). It is this hyperpolarisation which enables the photochemical apparatus of the outer segment to transmit its state as a nervous impulse. It is, however, difficult to see how the absorption of a single photon by the plasma membrane could cause a reduction in dark current by as much as 3% (ref. 5). Moreover most, if not all, of the light absorbing molecule, rhodopsin, is located not in the plasma membrane of the ROS but in the intracellular disks which are not connected directly to the outer plasma membrane[5,6]. These observations suggest that a transmitter is released from the ROS disks which interacts with the outer plasma membrane lowering its permeability to Na^+ (refs 3 and 7). Hagins[3,7] has suggested that the transmitter may be Ca^{2+} as treatment of ROS with Ca^{2+} causes their hyperpolarisation[7,8], and isolated ROS disks show an active uptake of Ca^{2+} (ref. 9). A light-induced efflux of calcium from ROS disks has also been described[10–13]. These observations indicate that even if Ca^{2+} is not the actual transmitter, it will have an important role in modulating the transmission of light as a nervous impulse.

There have been several reports that phosphorylation of plasma membrane proteins from liver[14], heart[15,16] or skeletal muscle[17] can increase the binding of Ca^{2+} to these membrane fragments. For this reason we investigated the effect of phosphorylation of rhodopsin on the Ca^{2+}-binding and permeability properties of ROS disks. /

ROS were prepared from calf eyes as described previously[18] and disk membranes and membrane fragments obtained by centrifugation at 10^5g for 60 min after rupturing the ROS outer

membrane by homogenisation in 10 mM Tris-HCl, pH 7.5 (ref. 19). The binding of Ca^{2+} to the disk membranes was determined after incubating to equilibrium as described in Fig. 1, from which it may be seen that there is little difference between membranes of ROS disks that have been kept in the dark, exposed to light or exposed to light and phosphorylated; although exposure to light and, in particular, phosphorylation of the light-exposed material, did cause some slight increase in Ca^{2+} binding. It has recently been reported that the amount of Ca^{2+} bound to ROS was greatly increased on exposure to light[12]. This result was probably obtained because incubations were not carried out for sufficient time to reach equilibrium (Fig. 3).

We next examined the effect of light on the rate of Ca^{2+} loss from ROS disks. Figure 2 shows that if the disk membranes were exposed to light before loading with $^{45}Ca^{2+}$ the subsequent efflux of radioactivity on suspension in Ca^{2+}-free medium was greater than that observed if the material was kept in the dark. The effect was prevented if the light-exposed material was phosphorylated by incubation with MgATP. Incubation with ATP in the absence of Mg^{2+} gave no effect. A similar effect of light was found whether the ROS disks were illuminated before or after loading with $^{45}Ca^{2+}$. As exposure to light causes, if anything, a slight increase in Ca^{2+} binding (Fig. 1) the increased $^{45}Ca^{2+}$ loss on exposure to light can scarcely be the result of an effect on binding; similarly phosphorylation causes such a small change in binding to light-exposed material that it is probably not important in affecting the rate of ^{45}Ca loss. It seems probable that Ca^{2+} entered the disks during incubation with $^{45}Ca^{2+}$ and that exposure to light increases calcium loss on suspension in Ca^{2+}-free media because of an increase in permeability of the disk membranes which makes it easier for Ca^{2+} to leave the loaded saccules, whereas phosphorylation of the light-exposed material lowers the membrane permeability.

If ROS disks which have been exposed to light are indeed more permeable to Ca^{2+} then the rate of entry of Ca^{2+} should also be increased. This was, in fact, found to be the case (Fig. 3); if the light-exposed material is phosphorylated then the rate of Ca^{2+} entry is lowered to a little less than that observed in material kept in the dark. Results shown in Figs 2 and 3 are thus comparable.

Reports have shown a decrease in bound Ca^{2+} on exposure of ROS to light[10–13], but it was not possible from those experiments to know if the result was the result of a reduction in

Fig. 3 Effect of light and phosphorylation on the rates of entry of Ca^{2+} into ROS disks. Freshly prepared ROS was either kept in dim red light (●), exposed to white light (▲), or exposed to white light and phosphorylated (■), and all samples washed with 10 mM Tris-HCl, pH 7.4, as described in Fig. 1. Disks were then suspended at a protein concentration of about 0.3 mg ml^{-1} in 10 mM Tris-HCl, pH 7.4, containing 0.3 M sucrose and 10 μM $^{45}CaCl_2$ (specific radioactivity 2×10^7 c.p.m. μmol^{-1}). Samples (0.5 ml) were taken at stated times and filtered to determine the amount of bound $^{45}Ca^{2+}$ as described in Fig. 1. Similar results have now been obtained in four separate experiments.
Ca^{2+}-binding sites or of a change in permeability. Our results clearly demonstrate that a change in permeability occurs.

If one accepts Hagin's hypothesis that a nervous impulse is triggered from ROS by the release of Ca^{2+} from the interdiskal space, then the observation that phosphorylation of bleached rhodopsin in the disks blocks the release is one of considerable importance. When light reaches the outer segments of the retina in the intact eye rhodopsin molecules will be bleached and a release of Ca^{2+} from the disks will certainly result. Within a fairly short time, however, bleached rhodopsin molecules will be phosphorylated and as this will lower Ca^{2+} permeability of the disks, they will be able to pump back Ca^{2+} from the extradiskal space. Such a mechanism would have considerable importance in the adaptation of retinal sensitivity to background light conditions. It is well known that the eye becomes progressively less sensitive with increasing background illumination; it seems likely that the fact that in such conditions increasing numbers of receptors are 'switched off' by phosphorylation will be of considerable importance in this phenomenon. On exposure to dark conditions the bleached rhodopsin will be regenerated and dephosphorylated so that the light receptors will be 'switched on' again, a fact which is likely to have considerable importance in dark adaptation. The time course of the loss of phosphate from phosphorylated rhodopsin in the intact frog retina is indeed the same as the time course of dark adaptation[20].

Plasma membrane fragments from many tissues, including brain[21-23], heart muscle[23,24], kidney[23] and liver[23], contain tightly bound kinase enzymes responsible for the phosphorylation of the membrane proteins. In these cases cyclic AMP stimulates the enzyme and has also been shown to cause an increase in efflux of Ca^{2+} from the kidney collecting tubule[25,26] or liver slice[27,28], and an increase of Ca^{2+} uptake into rat heart microsomal fragments[29,30]. Several workers have shown that phosphorylation of membrane proteins from liver[14], skeletal muscle[17] or heart muscle[15,16] causes an increase in Ca^{2+} binding, but no attempts have been made to measure possible changes in Ca^{2+} permeability. In the case of toad bladder, however, cyclic AMP causes an increase in the efflux of ^{45}Ca^{2+} presumably as a result of an increase in permeability[26,31]. In this tissue cyclic AMP stimulates the loss of phosphate from plasma membrane proteins, thus lowering the concentration of protein-bound phosphate[32]. Thus, in the toad bladder cell membrane, a decrease in protein-bound phosphate is associated with an increase in permeability to Ca^{2+}, whereas in ROS disks an increase in protein phosphorylation is associated with a decrease in permeability to Ca^{2+}.

It may be seen therefore that in the case of membranes of both ROS disks and toad bladder increased protein phosphorylation is associated with a decrease in permeability to Ca^{2+}. We suggest that changes in the state of protein phosphorylation have a general role in regulating Ca^{2+} permeability and/or binding in the cell membrane.

Divalent cation ionophore A23187 forms lipid soluble complexes with leucine and other amino acids

THE *Streptomyces* antibiotic A23187, a divalent cation ionophore[1], has been used as a tool in studies of the role of calcium in several cellular phenomena[2-5]. A23187 has a much higher affinity for divalent than monovalent cations, and the increased permeability induced by this ionophore in cellular membranes favours calcium and magnesium. X537A, another divalent cation ionophore[6], also enhances fluxes of monovalent cations[7] and forms lipid-soluble complexes with noradrenaline and some other organic compounds[8]. A23187 has often been referred to as a specific divalent cation ionophore although, to our knowledge, the evidence for the specificity is restricted to the lack of interaction with common monovalent cations like sodium and potassium[1,2]. In this paper we report experiments which show that A23187 is able to form lipid-soluble complexes with leucine and other amino acids at concentrations as low as or lower than those needed to form similar complexes with calcium.

We have been studying the mitogenic effect of A23187 on human peripheral blood lymphocytes in culture (submitted for publication). During these studies we found that A23187, like the lectin mitogens[9], caused an enhancement of the rate of amino acid uptake by the cells within 3 h of culture. Unexpectedly, ethyleneglycol-*bis*-(aminoethylether)-tetra-acetic acid (EGTA) in concentrations which entirely blocked calcium uptake did not abolish the increased rate of amino acid uptake induced by the ionophore. We therefore examined possible direct interactions of the ionophore with leucine.

First, we investigated the effect of A23187 on the partitioning of L-leucine between an aqueous and an organic phase. ^{3}H-leucine and 10 μM A23187 in 1 ml phosphate-buffered saline (PBS) were shaken vigorously with the same volume of toluene–butanol (1:1 or 7:3 v/v) mixture[2,10]. The ionophore was able to increase the proportion of ^{3}H-leucine recovered in the organic phase by 5 to 20-fold (Table 1).

In preliminary experiments we found that some organophilic impurity was present in the ^{3}H-leucine preparation. Therefore, in later studies the ^{3}H-leucine solution was extracted once with the toluene–butanol mixture before using it in the

Table 1 Organic sequestration of ^{3}H-leucine by A23187

Composition of the initial water phase	Amount of leucine in the organic phase after extraction	
	% c.p.m.	nM
Experiment 1		
Leucine (18.5 nM)	2.34±0.02	0.43
Leucine (18.5 nM+A23187 (10µM)	11.87±0.25	2.19
Leucine (18.5 nM), pre-extracted	1.56±0.01	0.29
Leucine (18.5 nM), pre-extracted+

[3]H-L-Leucine (1 µCi; 18.5 pmol); (Radiochemical Centre, Amersham, UK) in 1 ml PBS without divalent cations ± the ionophore as indicated was shaken with 1 ml toluene–butanol mixture for 1 min at room temperature in a conical glass centrifuge tube. Phase separation was facilitated by brief centrifugation. Aliquots of both the organic and the water phase were counted for radioactivity in identical conditions in a toluene-based scintillation cocktail. Total recovery of counts was more than 97%. Mean and range of the results from duplicate extractions are given. Approximate nM concentration of leucine in the final organic phase is calculated from the c.p.m. assuming that 100% of the radioactivity represents leucine.

Experiment 1: pre-extracted = ^{3}H-leucine stock solution extracted once with toluene–butanol before use in the actual experiment. Toluene–butanol ratio 1:1 v/v.

Experiment 2: Toluene–butanol ratio 7:3 v/v. % c.p.m. in cycle II is calculated with reference to the total amount of radioactivity in cycle II.

actual experiment. This procedure did not affect the A23187-induced sequestration of ^{3}H-leucine (Table 1, experiment 1). As the 10 mM stock solution of the ionophore was made up in ethanol, we included 1% ethanol in our controls. No significant increase in the proportion of ^{3}H-leucine in the organic phase was seen (Table 1, experiment 2). The A23187-induced sequestration of leucine was to a great extent reversible, as shown by re-extracting the organic phase with PBS (Table 1, experiment 2). As the vast majority of the ionophore is retained in the organic phase in these conditions[10], this finding suggests that some of the lipid-soluble complexes formed by leucine and the ionophore are dissociated during re-extraction with an aqueous phase. That the sequestration of ^{3}H-label by A23187 really represents transfer of leucine to the organic phase, and not that of a hypothetical radioactive impurity, was finally shown by displacing ^{3}H-label from the organic phase by unlabelled leucine (Table 2). These experiments also demonstrated that the molar ratio in the complexes formed by leucine and A23187 may be as high as 1:2, which is the figure reported for the divalent cation–A23187 complexes[3,10]. Ionophore (10 µM) was able to increase the concentration of leucine in the organic phase up to 6 µM (Table 2). Direct

measurements of leucine and ionophore concentrations are, however, needed to establish this ratio. Compared with cold leucine, $CaCl_2$ was clearly less effective in inhibiting sequestration of ^{3}H-leucine (Table 2). On the other hand, leucine seemed to be practically unable to affect the transfer of [45]Ca to the organic phase (Table 2). These findings could be explained by assuming that leucine and calcium are bound to different sites in the ionophore molecule, or that the $(A23187)_2$–Ca complex is not accessible to leucine, whereas complexes formed by the ionophore and leucine are sensitive to calcium ions. These competition experiments were complicated by the finding that 100 µM A23187, which was the concentration necessary to obtain significant sequestration of [45]Ca, was practically unable to transfer leucine to the organic phase, whereas such transfer was marked with the 10 µM concentration of the ionophore (Fig. 1). Almost identical results were obtained in three separate experiments. Higher concentration of ethanol in the 100 µM A23187 system was not the reason for the difference between the effects of 10 µM and 100 µM ionophore, as the presence of the same concentration of ethanol in the 10 µM system had no effect on sequestration of leucine or calcium (data not shown). We do not know the reason for the failure of 100 µM

Table 2 Competition between leucine and calcium for A23187

Composition of the initial water phase	% c.p.m. recovered in the organic phase	Organic sequestration % Inhibition	Calculated µM concentration of leucine or Ca in the final organic phase
[3]H-leucine (0.0185 µM)+A23187 (10 µM)			
+PBS	8.90±0.32	—	0.0016
+L-leucine (50 µM)	3.13±0.64	65	1.57

+CaCl₂ (500 µM)	5.1±1.2	65	25.54

Isotope (1 µCi; Radiochemical Centre) and the additions indicated were extracted with 1 ml toluene–butanol (7:3 v/v) mixture as described in Table 1. Approximate concentrations (µM) of leucine and calcium, respectively, in the final organic phase are calculated from the c.p.m., assuming that the affinity of the unlabelled compound for A23187 is identical to that of the respective radioactive isotope. Mean and range of the results from two separate extractions are given.

Table 3 Inhibition of ^{3}H-leucine sequestration by other amino acids and calcium

Composition of the initial water phase	Amount of ^{3}H-leucine in the organic phase after extraction		% Relative inhibition (mean)
	c.p.m.	μM (mean)	
^{3}H-leucine (50 μM)+A23187 (5 μM)	7,102±53	0.890	—
^{3}H-leucine (50 μM)+A23187 (5 μM)			
+L-leucine (50 μM)	5,678±322	0.710	100
+L-glycine (50 μM)	5,723±293	0.715	97
+L-lysine (50 μM)	5,832±122	0.725	89
+L-arginine (50 μM)	6,025±585	0.750	79
+L-aspartic acid (50 μM)	6,125±535	0.765	69
+L-glutamic acid (50 μM)	6,805±545	0.850	21
+β alanine (50 μM)	7,343±42	0.915	0
+ε amino caproic acid (50 μM)	7,458±178	0.930	0
+CaCl$_2$ (50 μM)	6,730±320	0.840	26

^{3}H-leucine (1 μCi) and the additions as indicated were extracted with 1 ml toluene–butanol mixture as described in Table 1. Relative inhibition of ^{3}H-sequestration by the added compounds is calculated from the c.p.m., taking the inhibition caused by 50 μM L-leucine as 100%. Mean and range of the results from two separate extractions are given.

A23187 to sequester leucine, but it could be explained by assuming that in an aqueous medium the highly hydrophobic A23187 can acquire two different micellar forms, depending on concentration. At lower concentrations of A23187 a form with a relatively high affinity to leucine is prevalent, whereas at higher concentrations the ionophore exists mainly in another form, which can bind calcium but not leucine. The final answer to this question requires further study.

We also found that leucine is not the only amino acid with which A23187 can interact. Whereas the partitioning of ^{3}H-uridine and ^{3}H-thymidine remained practically unaffected at 0.1 to 10 μM concentrations of the ionophore (data not shown) ^{35}S-methionine was effectively transferred to the organic phase by 10 μM A23187 (Fig. 1). Furthermore, several other α amino acids were able to inhibit organic sequestration of ^{3}H-leucine. They showed increasing relative affinity for the ionophore in the following order: Glu ≤ Asp < Arg < Lys < Gly < Leu (Table 3). Other experiments have shown that cysteine and glutamine can also inhibit sequestration of ^{3}H-leucine. Non-α

amino acids tested, β alanine and ε amino caproic acid, did not show any affinity for A23187 in this system (Table 3). Again, compared with cold leucine, CaCl$_2$ was less effective in inhibiting ^{3}H-leucine sequestration (Table 3).

The relevance of these findings to the effects of A23187 on cellular physiology is difficult to assess. Although we detected EGTA-resistant induction of an enhanced rate of leucine uptake within a few hours in lymphocyte cultures incubated with the ionophore, our attempts to show direct facilitation of leucine uptake in the presence of A23187 have so far been unsuccessful. Nevertheless, the findings reported in this paper indicate that the ionophore A23187 can cause reversible organic sequestration of amino acids at concentrations as low as, or lower, than those needed to form lipid-soluble complexes with calcium, and that equimolar concentration of calcium can only slightly inhibit this complex formation. This means that apart from the well documented action of A23187 as a potent divalent cation ionophore it may have effects on cellular metabolism resulting from its affinity for amino acids. One other implication of these findings is that when A23187 is used in complex experimental conditions, caution is necessary before concluding that all the phenomena detected are simply caused by increased permeability of membranes to divalent cations.

Fig. 1 Dose dependence of sequestration of ^{3}H-leucine, ^{35}S-methionine and ^{45}Ca into organic phase by A23187. Radioisotope (1 μCi) and indicated concentrations of the ionophore in 1 ml PBS were mixed with 1 ml toluene–butanol (1:1 v/v) mixture and shaken vigorously for 1 min at room temperature. Initial concentrations in the water phase were: ^{3}H-leucine, 18.5 nM; ^{35}S-methionine, 8.0 nM; ^{45}CaCl$_2$, 800 nM. For other experimental details see Table 1. Mean ± s.d. of two to four experiments are given. ●, Leucine; ■, methionine; ▲, calcium.

Corrigendum

In the article "The function of phytochrome in plants growing in the natural environment" by M. G. Holmes and H. Smith (*Nature*, 254, 512; 1975) the two arable weeds used were *Tripleurospermum martimum inodorum* (scentless mayweed) and *Chenopodium album* (fat-hen).

reviews

HERE is something to hold on to when exploring the complex terrain of animal learning. Professor Mackintosh has given us a book* that is detailed, authoritative and scholarly. In this age of symposia and multiauthored volumes, it is a rare treat to find a work of this magnitude by a single author, and even rarer to find one with an incisive and economical style. It is a large book, with more than 600 pages of text and over 2,000 references. It is also often a tough book, not only because its author does not hesitate to deal with complicated issues and material, but because his very economy of style does not cushion the reader with redundancy. It is a book to read without blinking, if not unblinkered. More than that : it is to be reread and kept as a source of relevant literature and of perceptive commentary and sophisticated analysis. Both the student and his mentor will be grateful.

The subject matter is conventional and traditional to experimental psychology—at least, it used to be traditional. It deliberately avoids the ethologists' concern with differences in creatures' capacities forced on them by particular evolutionary pressures "Although there may be important differences in the processes of behavioural modification to be found in different animals, the study of those processes, independently of any particular concern for their specialisation in different groups, remains an important and valid branch of science. Just as the sciences of genetics, embryology, and neurophysiology were initially advanced by the search for general, fundamental principles, undertaken with subjects chosen solely for reasons of convenience, so it is reasonable to suppose that some principles will have emerged from the analysis of associative learning in dogs, rats and pigeons. It is, at any rate, this tradition, started by Thorndike in America and, more systematically, by Pavlov in Russia, that forms the subject matter of this book." (p.3).

As such, a large portion of the volume concentrates on the details and theoretical underpinning of Pavlovian and instrumental conditioning in the dog, rat and pigeon. The first really influential book that attempted to contrast and dissect these two learning

*The Psychology of Animal Learning. By N. J. Mackintosh. Pp. xiv+730. (Academic : London and New York, December 1974.) £8.00; $18.50.

paradigms was Conditioning and Learning, by Hilgard and Marquis in 1940, and the comparison with the present work is of some interest. The empirical evidence now has swollen, almost, some would say, to the point of diminishing returns in a few areas of concentration. Not surprisingly, it has also become fragmented and there has resulted, Mackintosh fairly points out, "a severe failure of communication between workers in closely related areas. Thus [for example] the analysis of reinforcement in classical condition-

Careful tread on classic ground

L. Weiskrantz

ing has had little impact on theories of instrumental learning "

Mackintosh goes a long way towards re-establishing these lines of communication, and he can draw on recent advances that, somewhat overdue, have flowed from the liberation of behavioural analysis from the apparatus and paradigms that in the past have been taken almost as definitions of a particular type of learning. Thus, the discovery of autoshaping has planted a classical conditioning colony right in the middle of the instrumental conditioning reservation. Further, almost wholly new areas of interest have emerged; for example, contrast effects earn a whole chapter in Mackintosh's book whereas the term was not even known to Hilgard and Marquis, and in general the findings and experimental niceties of the operant conditioning movement are seen throughout this volume. Significantly, Hilgard and Marquis devoted hardly any space to the analysis of punishment, either theoretical or empirical, and Mackintosh's account of this important area is especially useful and succinct. Finally, it is interesting that Mackintosh—in a much stouter volume—foregoes discussion of some of the final chapter headings of Hilgard and Marquis—for example, neurophysiological mechanism and personality (both of deep concern to Pavlov)—and only touches briefly on the question of problem solving. One suspects that it

was not solely for reasons of limitations of space that this self-restraint was exercised.

It is fair to ask whether new principles have, in fact, emerged from persisting with the traditional account of associative learning in animals, as Mackintosh thinks it reasonable to suppose will have happened. Certainly, many new assertions about limited domains have emerged, but the striking strength of this book is its disavowal of easy generalisations; it takes complexity seriously, and abounds with qualifications and counter-arguments, laced with scepticism. Talking about schedules of reinforcement, a prime source of generalisations for some researchers, he says "They are frighteningly complex and not necessarily at all well suited to an elucidation of the important processes underlying instrumental behaviour. Too many variables are permitted to vary in too many ways for it to be easy to achieve any analytic understanding." At the same time, he is prepared to defend unpopular theories, such as the stimulus-substitution theory of classical conditioning. Elsewhere he is at pains to blur accepted distinctions, as when he argues that the difference between response systems of classical and instrumental conditioning is one of degree, not of kind. Overall, the case for dealing with associative learning in animals, independent of particular specialisations, is well sustained, though whatever else this volume provides, it is not a compendium of fundamental principles. But progress in this field need not suffer on that account. In some other areas of biology, such as neurophysiology, we continue to see significant advances based on the gradual accumulation of evidence combined with careful empirical and logical dissection of the controlling variables and the underlying mechanisms, rather than the all-embracing insight or sudden breakthrough.

Beyond the domain of conditioning and the excellent extensions into discrimination learning, contrast, and generalisation, one will not find much argument or space devoted to cognitive capacities commonly appealed to in studies of human learning that might also seem applicable to learning in other mammals. Even place learning, long a favourite of the animal 'cognitive' theorists, is relegated to minor importance. Learning-set phenomena are discussed only briefly. New fron-

tiers may not be broached, but a large
and strategically located segment of the
Old World has been extremely well
charted. One will have to look hard
for a better guide to a region that is
criss-crossed with well trodden paths
but still nourishes a fresh crop of deli-
cate fruit and nettles each spring. For
someone who wants to keep his feet on
the ground, nettles really matter. □

Simply chemistry

Chemistry. By Linus and Peter Paul-
ing. Pp. xi+767. (Freeman: San
Francisco, 1975.) $13.95.

THIS is essentially a new edition of the
elder Pauling's highly successful
General Chemistry. The original text
has been shortened in places, largely by
the omission of much of the thermo-
dynamic material, and the scope has
been expanded by the addition of an
extensive and well balanced treatment
of molecular biology, in which most of
the important macromolecular struc-
tures are discussed. This change reflects
not only some shift in the research
emphasis of chemistry itself but also in
the new audience for whom this book
has been specifically designed, namely
"students primarily interested in bio-
logy, medicine, human nutrition, and
related fields". It provides thus a broad-
brush picture of the whole of chemistry
(inorganic, physical, nuclear, organic,
and biochemistry) and its interaction
with the biological sciences, at a level
suitable for those first studying it at an
American college.

The emphasis throughout is on the
structural aspects of chemistry, even
more so than in the previous editions.
For many chemists the chief demerit
of *Chemistry* will be its heavy reliance
on electronegativity, resonance, the
electroneutrality principle, and other
concepts familiar to readers of *The
Nature of the Chemical Bond* but less
obvious in most of the current che-
mical literature: the authors would
presumably defend their point of view
as being simple, general, and par-
ticularly suited to the limited chemical
sophistication of their intended readers.
Others may cavil at the slight reference
to modern physical techniques and
organic reactions and their mechanisms.
The exposition, which is delightful
with its clarity and elegance of style,
will appeal to the student and arouse
his or her interest with its neat and
modern choice of example and illustra-
tion. There are numerous sensible,
straightforward, and intriguing prob-
lems and the diagrams are excellent. I
much enjoyed reading it, and so did
my daughter, now in the middle of a
sixth form science course. By modern
standards the book is very modestly
priced. **C. S. G. Phillips**

From cell to cell

Cell Communication. (Wiley Series in
the Dynamics of Cell Biology.) Edited
by R. P. Cox. Pp. ix+262. (Wiley: New
York and London, November 1974.)
£11.90.

ONCE again we are victims of editorial,
or perhaps publisher's pride—this book
is not about all aspects of cell com-
munication for it treats only a limited
number of features of the subject. But
there is one strong, important theme of
the book: it contains three good re-
views on the related subjects of 'tight
and gap junctions', 'low-resistance path-
ways' and 'metabolic cooperation'. The
remaining eight papers cover an assort-
ment of subjects in which cell com-
munication plays a greater or lesser
role but no particular theme joins them
or excuses the absence of so many
aspects of cell communication. The
diligent reader will note the lack of any
mention of exo and endocytosis, cell
fusion (both in fertilisation and in other
contexts), cell adhesion, cell positioning
and recognition phenomena, malig-
nancy, and anything at all about plants.

The electron microscopists seem at
last to have abandoned their addiction
to neoclassical microanatomical latinity
and the excellent article by Norton
Gilula shows how *zonulae occludentes*
have become tight junctions. But this
is not the main virtue of his article.
That lies in the beautiful electron
micrographs of the specialised contacts
between cells which are probably the
low-resistance routes between cells and
the pathways for interchange of
metabolites between cells. This article
summarises work from several labora-
tories, published in the past few years.
Judson Sheridan explains the main
observations carried out on low-
resistance pathways and the editor and
his coworkers review "Metabolic co-
operation". In spite of the suggestion
that appears in these three articles—
that the three phenomena are but
aspects of the same matter—it is still
unclear as to how important the
phenomena are in the real life of an
animal.

The remaining articles in the book
cover an assortment of subjects. Note-
worthy are those by Harry Rubin on
cell growth—a process in which cell
communication may be unimportant—
and by Albert Harris on contact in-
hibition. There are also papers by
Fishbach on neuromuscular junction
formation, Kolodny on transfer of
macromolecules between cells, Cruik-
shank on cell interactions in the skin,
Basten and Miller on the immune
response, Neufeld on lysosomal diseases
and Ottolenghi-Nightingale on DNA
transformation in mammalian cells.
Adam Curtis

ABOUT a century ago science was in the grip of a surging interest in psychical research. In laboratories, both amateur and professional, literally hundreds of earnest scientists were conducting experiments of the most extraordinary kind—bottling ectoplasm, weighing mediums while in and out of trance, photographing materialised spirit forms, and so on. Though it may seem that such activities were at serious odds with the 19th century mechanistic view of the Universe, on second thought they seem less incongruous. Most of these pioneers were raised and educated within the ethos of Victorian Christianity which held that man was essentially an immortal spirit for whom death was a transition and not an extinction point. Furthermore, they were also steeped in the notion of the infallibility of the 19th century scientific method—everything in the Universe was fit and ready for instant laboratory investigation. Thus the weird phenomena of psychic research were no more elusive in principle than the behaviour of molecules or planets.

The rollcall of personalities involved in that phase of psychical research is breathtaking and includes Lodge, Rayleigh, Freud, Wallace, Richet, Crookes, Gladstone and J. J. Thomson, to name but a few; all came to believe that psychic research was one of the most important avenues of study for mankind, and incurred the contemptuous scorn of fellow academics as a result. Sir William Crookes for example, one of the most distinguished physicists of the century, participated actively in spiritualist seances and was so confident of his beliefs that he proudly allowed himself to be photographed arm-in-arm with a "materialised spirit form", a diaphanously garbed but otherwise rather earthy-looking being, known as Katie King.

Well, a 100 years have rolled by and, in spite of the sonorous declarations of Crookes and his contemporaries and the volumes of scientific papers on psychical research, who today—apart from a few ardent spiritualists—treats bottled ectoplasm or the photographs of the Crookes-Katie King encounter as anything other than fading curiosities? Worse still, who would argue that all the industry of those gallant pioneers and the stupendous cerebral effort they invested in chasing phantoms has improved our understanding of the Universe one jot?

I have to admit that disheartening reflections of this kind drifted through my head as I scanned through John Taylor's *Superminds**. The author is a

*Superminds: An Enquiry into the Paranormal. By John Taylor. Pp. 183. (Macmillan: London and Basingstoke, April 1975.) £3.95.

distinguished mathematician and physicist with an international reputation in his field. He is also at this time actively preoccupied with investigating phenomena which, if not actually involving ectoplasm and spirits appearing out of floors, will seem to most scientists to be more or less in the same category. The phenomena in question involve mysterious distortions in objects such as spoons, forks and metal bars, which are alleged to take place in the general vicinity of certain children. I say "in the general vicinity of" and yet, though most of the bendings and distortions —some of them are literally grotesque, as the book's numerous illustrations reveal—require the child to stroke or

Brave but not convincing

Christopher Evans
otherwise handle the metal, others allegedly take place at distances varying from yards to miles away from the 'bender'. As if that were not enough, the objects sometimes bend inside metal boxes, corked test tubes and even in locked cupboards.

Professor Taylor's interest in this peculiar pocket of the Universe seems to have been sparked by the notorious BBC television programme in which the flamboyant Uri Geller disintegrated a fork before an historically uncritical audience. This was followed by more closely controlled demonstrations in Taylor's laboratory at King's College, some of which unsettled him to the extent that, as he puts it, "the whole framework with which I viewed the world had suddenly been destroyed". From here there seemed no course but to continue the investigations through to the end, whether bitter or glorious, taking as subjects some of the children whose metal bending powers sprang into being following the television demonstration.

As a result Taylor is convinced that he is tapping and probing previously unknown forces of immense potential and significance, and his *Superminds* is in part a record of his findings and in

part an attempt at providing a theoretical framework for them. For the latter he leans on hypotheses invoking electromagnetism, mainly because no other kind of theory even remotely begins to fit the facts. The soundness of this theorising is a matter for discussion by other theoretical physicists but I must raise the strong suspicion that Professor Taylor is putting the cart before the horse. Before getting drawn into the complexities of theorising it is more economic to make absolutely certain that one has not only established the phenomena beyond all doubt, but that one has also satisfied oneself that these phenomena cannot be encompassed within any existing theory.

Unfortunately, though Taylor may well be convinced of this in his own mind, the material in the book will, I fear, do little to convince other scientists. My most serious objection is the ease with which he seems able to discount the possibility of fraud and deception; true, he has devised some elaborate apparatus—attaching the objects to spring balances to detect whether the benders are using physical pressure on them, and so on—but these precautions seem to me to be diversionary and indirect when more positive strategies could be used.

For example, if it is claimed that an individual can bend metal, within containers of various kinds, without touching it, then the first step should be to set up apparatus in an independent laboratory, using infrared beams to detect prying fingers, and videotape to record the metal as it distorts. Alternatively, if it is argued that laboratory conditions are inhibiting—Taylor comments, rather ingenuously, that the presence of "sceptics" tends to kill the phenomena—then all one has to do is to encapsulate metal bars in specially blown glass spheres which can be left for a given period in the homes of the 'superminds', and which can be inspected afterwards for signs of tampering. In fact, since writing *Superminds* Taylor has been attempting automation of his experiments, including constant videotaping, in an attempt to meet objections of this kind. The truth of the matter is, however, that if half of what is claimed on behalf of the superminds is true, then scientists and science in general deserve more solid data than he offers in this particular work. But it is still a brave book and Professor Taylor is a brave man to have written it. Alas it is the same kind of bravery, in my view, that Crookes exhibited when he took an alluring ghost by the arm and tried to convince the world of her reality. Crookes' contemporaries remained unconvinced, and so, I suspect, will Taylor's. □

obituary

Ernst F. W. Alexanderson died on May 14 at Schenectady, New York, where for so many years he was a rich source of ideas and inventions for General Electric. He was 97.

General Electric, USA

Alexanderson was born at Uppsala, Sweden and studied at the University of Lund and the Royal Institute of Technology in Stockholm. Shortly after graduating he was working in Germany when he saw a paper on 'Alternating Current Phenomena' by Steinmetz and decided to go to the United States and seek employment in the author's laboratory at General Electric. He went to America in 1901, started work under Steinmetz in 1902, and within a year had established a reputation as a designer specialising in alternating current generators. At this time, just after the turn of the century, commercial wireless telegraphy was well established, but the system most generally used was the fairly crude spark transmission, which radiated a damped wave train covering an inconveniently wide frequency band and which was unsuited to any modulation more sophisticated than the on–off keying of the Morse code. If a continuous, high frequency, sinusoidal voltage could be generated it would help solve the increasingly pressing problem of interference between simultaneous transmissions from neighbouring stations, and furthermore it would be a much more promising carrier for

modulation by speech or music. In 1904, Fessenden, who had carried out successful preliminary experiments with radio telephony, brought this problem to General Electric and asked them to design a high power alternator operating at a frequency of many kHz. The task was given to Alexanderson, and on Christmas Eve, 1906, Fessenden was able to broadcast speech and music. Work on thermionic valves proceeding elsewhere in the General Electric laboratories led to efficient methods of high power modulation, and Alexanderson's alternators, producing up to 200 kW, became the basis of many commercial and military radio systems during World War I. This strongly influenced the US Government to promote the formation in 1919 of the Radio Corporation of America, combining the radio interests of General Electric with those taken over from foreign companies who were excluded from the new organisation in the national interest. Alexanderson worked full-time for General Electric and RCA until he was seventy, and as a consultant until he was nearly eighty, pouring out inventions in fields as diverse as magnetic amplification, control systems, ship propulsion, aerial design, electronic circuitry and colour television systems. He was in the great tradition of American inventor–scientists and had well over three hundred patents to his name. Of his many honours, he was probably most gratified by a decoration from King Gustav V of Sweden and by the entirely appropriate award of the Edison medal.

G. K. T. Conn, OBE, professor of physics and head of the department in the university of Exeter since 1957, died on June 4 at the age of 64

After working on infrared and Raman vibrational spectra with Sutherland's group in Cambridge, he worked both at Sheffield and Exeter on the properties of solids (metals, alloys and semiconductors)—as determined by the evaluation of the optical constants for various frequencies. This involved determining the parameters of monochromatic radiation reflected from prepared surfaces; and the frequencies involved ultraviolet, visible, infrared and far infrared, including latterly the methods of Fourier transform spectroscopy. The methods he developed with Beattie and Eaton have been adopted by a number of other workers in the

field. He was editor of *Research*, a review journal, from 1956–62, and more recently had been joint editor of a series of Essays in Physics. He was also general editor of a series of textbooks, *The Modern University Physics Series*, in current production. His terms as deputy vice-chancellor of Exeter (1967–69) involved him in a series of delicate discussions during a period of unrest besetting British universities.

Hans D. Berendes, professor of genetics at the University of Nijmegen and well known for his work on gene action and chromosome structure, died on May 25 at the age of 41.

Berendes was born in The Hague and in 1955 began his study in biology at the University of Leiden. In the advanced part of his study he started research on the salivary chromosomes of *Drosophila hydei*, which dominated his whole scientific career, and completed a cytological map of these giant chromosomes. In 1962 he was appointed as lecturer at the University of Leiden. Impressed by the work of Beermann and Clever he worked on gene action in *D. hydei* as expressed in the puffing of salivary chromosome bands. He obtained his doctors degree in 1965 for a thesis on puffing patterns in the course of the late development of larvae and pupae, and the correlation between the appearance of some puffs and a cell product. In the same period he started research on the induction of puffs by external factors, in particular heatshocks. He then took a position in Beermann's laboratory at Tübingen, where he worked on the role of ecdyson in activation of puffs, puffing patterns in different tissues, protein metabolism in puffs, differential replication of chromosomal DNA and the electron microscopic structure of the salivary chromosome. In 1968 the Universities of Geneva and Nijmegen offered him chairs in Zoology, but he preferred to return to Holland to continue his work on *D. hydei*. Important papers appeared on the ultrastructure of DNA from the giant chromosomes, on the products of certain puffs, and on the relation between the formation of puffs and synthesis of mitochondrial enzymes. The latter project promises important insight into the regulation of gene activity in higher organisms. Berendes was also a very able organiser. He participated strongly in University affairs and in the Organisation for Pure Research (ZWO).

announcements

Award

Lynn R. Sykes has been awarded the **Walter H. Bucher Medal** by the American Geophysical Union for original contributions to the basic knowledge of the Earth's crust.

Appointments

P. J. Peterson has been appointed Royal Society visiting professor attached to the School of Biological Sciences at the Universiti Sains Malaysia.

James Brown, area engineer for Africa and the Western Hemisphere, Shell International, has been appointed to the new chair of petroleum engineering at Heriot-Watt University.

The University of Sheffield has made the following appointments: **N. M. Atherton** to a personal chair in chemistry; **G. Hudson** to a personal chair in experimental haematology.

Miscellaneous

Heinz Karger Prize. Heinz Karger Memorial Foundation invites papers on: methods for early diagnosis of genetic disorders (1976); and molecular biology of metabolic diseases (1977). Closing dates: February 28, 1976 and 1977. For conditions and further information, contact: S Karger AG, Arnold-Bocklin-Strasse 25, CH-4011 Basle, Switzerland.

Travel fellowships. The Winston Churchill Memorial Trust offers travel grants for 1976. This year's list of categories includes: teachers in further education, laboratory technicians, energy resources, naturalists, and conservation of coastal amenities. Further information and applications (UK citizens only): The Winston Churchill Memorial Trust, 15 Queen's Gate Terrace, London SW7 5PR, UK.

International meetings

August 21–23, Gamete competition in plants and animals, Lake Como, Italy (Dr D. Mulcahy, Universita di Milano, Istituto di Genetica, Via Celoria, 10, 20133 Milano, Italy)

August 21–27, Plant protection, Moscow, USSR (Professor V. A. Lebedev, Secretary General of the Organising Committee of the Seventh International Congress of Plant Protection, Orlikov per 1/11, Room 478, Moscow 107139, USSR).

August 22–29, Limnology, Winnipeg, Manitoba (Mr R. M. Raeburn, University Relations and Information Officer, The University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada).

August 23–27, Rheology, Gothenburg, Sweden (J. Kubat, Chairman, Organising Committee, Chalmers University of Technology, Fack, S–402 20, Goteborg 5, Sweden).

August 24–27, Crystal growth, Edinburgh, UK (F. W. Ainger, Allen Clark Research Centre, The Plessey Company Limited, Caswell, Towcester, Northamptonshire, UK).

August 25–29, Atomic spectroscopy, Clayton, Australia (Dr J. B. Willis, Secretary, Fifth International Conference on Atomic Spectroscopy, CSIRO Division of Chemical Physics, PO Box 160, Clayton, Victoria 3168, Australia).

August 25–29, Thin films, Budapest, Hungary (Organising Committee of ICT F3, 1325 Budapest, PO Box 76, Hungary)

August 25–29, Cybernetics and systems, Bucharest, Rumania (Dr J. Rose, Director General, World Organisation of General Systems and Cybernetics (WOGSC), College of Technology, Blackburn BB2 1LH, UK).

Good for people, bad for science

ONE of the merits of democracy is not simply that it gives people the chance to choose whom they want to govern but also that it gives them the chance to say whom they do not want. In particular the democratic process makes it possible to say to a government— enough, we don't like the way you do things, it's time to try another way. The ability to reject as well as to accept seems to be a necessary part of most human endeavour, at least any endeavour in which there is any concept of growth or evolution. Foolish would be the person prepared to take on any commitment from which there seemed to be no means of escape, if needed, and foolish are those who try to make the means of escape humiliating, expensive or distasteful.

The development of science also shows the rejection mechanism in action; not simply in the process by which the scientific manuscript has to stand the test of peer review, but also in the endless self-criticism which the good scientist applies to his ideas long before they are committed to paper and in the rapid way in which the scientific community works over published material seeking out errors and inconsistencies.

It is strange that, although we recognise the need that scientific ideas should not only have a platform but should also have to face a barrage of rotten eggs, we are unbelievably cautious when it comes to the scientist himself. If the idea doesn't make the grade, it won't last six months; if the scientist doesn't make the grade—well he's got tenure and could be around for another thirty years.

Job security is, of course, an excellent thing in many ways. It reassures those who set out on long and some- times tedious intellectual pathways that they are not going to have to worry about keeping in favour with their employer or about producing quick results simply in order to stay in business. It keeps the universities and the Civil Service away from any form of external threat to their pursuit of knowledge. But at what cost?

Tenure is a virtual guarantee that the system will either agree indefinitely to your doing what you want to do or that it will find you another job if the present one gets too much. This is a very humane and

enlightened practice but it bears little relationship to a world in which the demands on science are changing rapidly; it also takes no notice of the propensity of science to proceed by revolution. Further, although keeping in favour with one's employer is not necessary to being a good scientist, science, even within universities, does call for a certain amount of man- management, and the need for management is bound to increase. Yet if managers lack the ultimate sanction of being able to dispense with those who cannot or will not contribute effectively, management has one hand tied behind its back.

The pressures in recent years have been rather obviously towards increasing job security in universities (the Civil Service is already about as secure as the priesthood) and there is talk now of giving laboratory technicians some sort of tenure. Such pressures ought to be firmly resisted and, if anything, there should be serious discussions about reversing the trend. It would obviously be silly to put the academic or governmental scientist on to a three-months' notice basis, but few could complain of indecent haste if a contract came up for renewal on both sides once every ten years. There might be stronger support for such an idea within the scientific community than is generally realised.

Such a procedure would also permit the at present almost impossible operation of closing down a depart- ment to be carried out relatively bloodlessly within the space of a few years when necessary.

The standard objection to any loosening of the tenure grip is to point to the problems of those who would be turned out after many years of service. The answer to that is that there are already many careers in which there comes a day of reckoning; perhaps the most analogous is the military profession. If the change is intelligently anticipated and financially assisted there is no reason why it should be a humiliating experience at all. Indeed, for all we know, the release every year of a few hundred scientists into a more general environ- ment might encourage industry and commerce to use them imaginatively. After all, not every retired Major runs a sweet shop.   □

IFIAS: the top people's problem posers

The International Federation of Institutes for Advanced Studies aims to mobilise a global intellectual community to examine problems which have not been officially recognised and subjected to political convenience. Wendy Barnaby reports.

THE last few years have seen an upsurge in discussions about the social responsibilities of scientists. From Koestler's "Callgirls" to articles in the daily press, the familiar message has been that science is not an activity which should be broken up into discrete categories and carried on in laboratories isolated from moral issues and awareness of the directions in which societies are developing. Such sentiments have already—unfortunately— become platitudinous. So it is rather a shock to discover a potentially high-powered organisation which exists to put them into action.

The International Federation of Institutes for Advanced Study (IFIAS) is a loosely-structured conglomeration of some twenty research institutes in sixteen countries. It is a unique federation because the institutes cover at least ten very different disciplines and co-operate on scientific projects which they hope will contribute to the solution of some of our global problems.

The federation was set up in 1972 with $90,000 in equal grants from the Nobel, Rockefeller and Swedish State Bank Foundations. It is non-profit making, and non-governmental, with headquarters at Stockholm in three small rooms in the Nobel House, where its secretary, Dr Sam Nilsson (a physicist), also lives. Its structure and methods of working are very flexible: it is not so much an organisation, says Dr Nilsson, as a lack of organisation. General guidance on the course to be followed and on specific projects is given by the directors of the member institutes, a board of trustees (whose Chairmen are Drs Alexander King (UK), Paul M. Fye (USA), Abdus Salam (Pakistan) and Victor Urquidi (Mexico)), and a panel of advisers in different fields who have participated in IFIAS work. The secretariat is the go-between for the institutes, and initiates and catalyses new projects. It has been supported, after the exhaustion of the initial funds, by $150,000 a year, a sum made up of annual fees from member institutes, each of which pays 0 5% per 1,000 units (whether dollars, yen, rupees or whatever) of its operating budget, and grants to be paid for 5 years by foundations and similar bodies in Sweden ($35,000 each year), USA (also $35,000), Japan ($10,000), Italy ($5,000) and France ($5,000). Each institute taking part in a project also pays a levy of 10% of its contribution to the project. These levies are the secretariat's third source of income.

The institutes themselves specialise in fields including oceanography, medicine, physics, humanistic studies, economics, ekistics (the study of human settlements), genetics, international relations, rice research, mathematics and insect physiology and ecology. Together they represent 5,000 researchers and over $100 million in annual expenditures.

IFIAS' intention is to mobilise this global intellectual community to examine problems which have not been officially recognised and subjected to political convenience. It is the belief of the federation that more effective communication must be stimulated between, on the one hand, those who make the decisions involving long-term consequences for mankind, and, on the other, the world's intellectual and spiritual leaders. By choosing as-yet politically-uncontaminated areas of study, and by consulting and involving the decision makers in projects from the very beginning, IFIAS hopes to bring the influence of facts and well-considered alternatives to bear on the decision makers when they have to act. The emphasis is on working with decision makers rather than presenting them with tomes of conclusions which will never be read. By making use of the contacts of its members, the federation has been able to adopt a policy of dealing only with top people, whether politicians, bureaucrats, businessmen or scientists, and so has a greater potential for influence than most organisations.

Specific action requires a specific focus. Every project is therefore concrete, complex, budget- and time-limited, global in scope and involving inter-disciplinary research. Participation in projects is not limited to member institutes. Other research bodies take part when their expertise is needed, and in this way various UN agencies— UNESCO, WHO, the UN Environment Programme (UNEP) and the World Meteorological Association (WMO)— are involved in different projects. No proposal for a new project is accepted before it has been extensively screened at workshops to make sure that nobody else is doing it better, that at least two member institutes from different countries are willing to assume responsibility for it, that a specific scholar is willing to lead it, and that it has social, ethical and humanistic implications and financial support. When a topic is first accepted, IFIAS sets up a programme of activity which may or may not develop into a full-scale project. So far, funding has come from the World Bank, Volkswagen, the Ford and Rockefeller Foundations, UNEP, UNESCO and the Swedish agency for aid to developing countries (SIDA). To promote contacts with those who wield power over hundreds of thousands of lives, and to attract funds, IFIAS has also begun to approach international corporations.

The programmes and projects so far in operation are:
- Impact of climate changes on the character and quality of human life (budget: $300,000)
- Human settlements: understanding their nature and guiding their development for the benefit of man ($325,000)
- Socio-economic and ethical implications of enzyme engineering ($194,000)
- Energy and quality of life ($80,000).

These programmes and projects are being screened:
- Options for regions faced with water shortage
- Interaction of health, nutrition and education on human growth and development
- Loss of productive soil
- Third world: cultural transfer— cultural change
- Independence and interdependence in the face of regional collapses.

The projects are not concerned with research which gives rise to predictions about resources, climate changes or urbanisation for example. As Dr Nilsson points out, there is a wealth of such predictions already. IFIAS sees its task as examining their consequences. The human settlement project starts from the prediction that by the year 2000, 50% of the estimated world population of 6.5 billion will live in cities. The rationale of the project is that, as these cities will be built anyway, they should be planned in order to conserve resources and promote the best possible living conditions for their inhabitants.

The project aims to draw up a classification of human settlements and, through case studies from Sweden, France, Mexico, India, USA, Columbia and Argentina, to establish criteria for understanding their development. It is hoped that the project will arrive at a conceptual framework which could point to practical suggestions for the UN Conference-Exposition on human settlements (HABITAT) to be held in Vancouver next year.

The project on climatic change is

being carried out against the background of predictions that climatic alterations will soon threaten existing systems of food production. In the face of conflicting predictions about the changes and their effects, the project has adopted the general IFIAS method of dealing with a range of predictions varying from the least to most drastic. What is 'drastic' to begin with is then defined by the general criteria for project selection, mentioned above. The researchers are aiming for plans and actions to establish the technical, social and political means to cope with different climatic threats to food.

The energy programme is in two parts. The first is concerned with energy analysis, which is the idea of working out how much energy is embodied in goods or services, expressed as physical units Undertaken in the light of predictions that, because of limited resources and extravagant use, energy may become a severely limiting factor in many sectors of society, energy analysis includes not only the direct energy used for fuel and to run machinery, but also the energy required to make available each of the input materials. For example, in an industrialised country a loaf of bread is the end product of seed which grows through the absorption of energy (partly from natural sources, partly from petroleum made into fertiliser) into grain, which is harvested, transported and processed into flour by machines, then transported again and added to other ingredients (all of which have arrived at this point through similar processes), mixed and baked by more machines into bread (which is possibly wrapped in paper that is the end product of another energy-consuming chain), and finally transported by petroleum-eating lorries to the super-markets.

Because energy analysis is value-free, it can provide information, in addition to the predictions of our all-too-fallible economic theories, for decision making. It appears to be neither costly nor difficult to carry out, as much of the data needed already exist in national statistics, industrial process data and various other sources. The urgent need is for a common set of rules for calculating energy inputs and transformations, and for common terminology, symbols and units of measure. It is these that the IFIAS project is drawing up.

Once the tools are agreed upon, researchers in different countries will be able to calculate the energy inputs into similar products and identify steps where the use of energy could be reduced. Or the analysis could be used to compare the anticipated energy saving of a development—house insula-

tion, for example—with the initial energy investment necessary to create the development. The energy impact of recycled materials could be assessed. And industries and governments would be able to examine the energy implications of their decisions.

The second part of the energy project is entitled "Alternative Choices of Level of Energy Consumption in Different Societies" Although it is usually taken for granted that a linear relationship exists between energy consumption *per capita* and GNP *per capita*, this is actually true only in energy-affluent societies. The project is analysing why a certain country can achieve the same GNP *per capita* as another country but with a much lower consumption of energy The study is aiming at comparative analyses of different socioeconomic trade-offs in different countries (for example Scandinavia, Japan, India, Kenya) at varying levels of energy consumption rates (say 4%, 2% and 0% a year)

The project on enzyme engineering is typical of the scope and, in its relevance to developing countries, of the emphasis of IFIAS work. Enzymes are of course already widely used on a 'use-and-throw-away' basis to support a variety of socially necessary processes. But it was not until techniques were developed for immobilising enzymes on a support material that their catalytic activity could be retained for reuse, and this has reawakened interest in the use of enzymes as catalysts in many different areas. The IFIAS project is led by Professor Carl-Göran Hedén of Stockholm's Karolinska Institute and is being carried out by member institutes in France, Israel, India and the USA, as well as other institutes in the USSR, Sweden, Canada and the UK. UNESCO is also participating. The project is investigating the use of enzyme engineering in four fields: developing

enzyme-catalysed energy transfer devices which could increase the practical applications of fuel cells or use electrical energy to synthesise organic chemicals for industry, nutrition and pharmaceuticals; testing a quick, enzyme-dependent method of detecting tropical diseases such as malaria; developing a technique of giving the booster shot at the same time as an initial injection in immunisation (to solve the problems of finding people in developing countries when their booster is due); and improving biological control agents by means of enzyme attachment to insect pathogens.

Professor Hedén is enthusiastic about the potential of enzyme engineering in other areas as well. At a symposium in Tokyo last September he outlined an idea which entails a better use of resources for accelerated development in the Middle East. Pointing out that the methods of chemical catalysis currently used in the production of methanol need such high pressures and temperatures that only large-scale factories are competitive, he proposed the use of enzyme catalysis in conjunction with natural methane flares, which today burn as waste, to produce methanol in small-scale plants. Such methanol could be used not only for making fodder protein and enzymes, but also as a cheap, high-octane and relatively clean fuel for cars, or as a safer medium than methane for the carriage of hydrogen.

Such "equilibrium technology"— processes and industrial equipment which use renewable energy sources and are geared to a maximum of recycling of matter—is typical of the inventiveness and optimism, some would say idealism, of the IFIAS approach. The attractiveness of Professor Hedén's scheme for the Middle East, for example, does not end with methanol technology. It also emphasises a range

of biological uses for solar energy ranging from waste treatment to fish farming. He envisages Arab countries such as Kuwait, whose national development plan is very conscious of, and aims for, a balance between ecosystems, providing the vision and financial resources for a regional development effort based on an international input of scientific manpower. This would help to make each side in the Middle East conflict dependent on the other for its future.

As none of IFIAS' projects has yet been completed it is too early to talk about their final results. Already, however, there are signs that IFIAS' work is not going unnoticed. The Brussels headquarters of the Common Market has asked IFIAS for information about the energy analysis programme, and has reserved $100,000 for a joint IFIAS/Common Market project on energy. The Market is particularly interested in adopting IFIAS' methodology for working out alternative levels of energy consumption, with a view to using the technique in drawing up a European energy policy. The World Health Organisation is also very interested in an IFIAS project; this time the one on enzyme engineering. WHO's attention is concentrated on that part of the project dealing with the new method IFIAS has developed for diagnosing tropical diseases. The method was tested in East Africa last February and looks promising.

The first evaluation of IFIAS will no doubt be the one planned by the organisation itself, to be conducted in 1977—five years after its inception. This idea is good in principle, but should not be expected to produce any rational calculation of its achievements. One of the problems involved is the lack of any concrete output or of any yardstick to measure it. Barring administrative incompetence, each team of institutes will obviously be able to produce lengthy documents supporting the results of its particular project. By then they will also perhaps be able to point to even more examples of their work being referred to by the decision makers.

The continuation of IFIAS will depend not on the results of 'evalua-tions' of its work but on the enthusiasm of its members. And nothing could be calculated to sustain that enthusiasm more than the sort of successes the energy analysis and enzyme engineering projects have already enjoyed. Convincing decision makers of the need for action may be harder in the project on climate change. The invisibility of the problem makes it an unlikely target for that public concern which, in countries where politicians depend on the people for their positions, can be an effective complement to IFIAS' high-level approaches in making the decision makers act. On the other hand, the problems dealt with in the project on human settlements are symbolised by the ugliness, dirtiness and congestion of modern cities. If handled properly, the project could have an impact on public policy. Unfortunately, the impact will be greatest if IFIAS keeps its activities separate from the UN conference towards which they are aimed; for incisive and intelligent proposals have a way of emerging from the politically-sensitive and grindingly slow UN machine in a very emaciated form. □

SOMEHOW or other, they had cajoled the money and effort to try their strange and fabulously expensive experiment. Many people said that the funds should be spent on something more useful, or not spent at all. But there was a great public curiosity in the idea; perhaps Orson Welles had helped as much as anyone with his radio broadcast of invaders from Mars in 1938 that caused a nationwide panic. Is there life on Mars? We were now ready to settle for a few anaerobic bacteria rather than green monsters with fusiform antennæ.

The Viking biology team had been called together by the team leader, Harold Klein, for the last time before the launch on August 11, 1975.

One year ago, our hope that even one of the three experiments would be ready by launch-time was a slender one. The constraints were severe; everything that is sent to Mars must be sterile. There is no use carrying bacterial spores from Earth to Mars to detect their presence later. It cost about a million dollars to sterilise the parachute, principally because no-one had ever sterilised a parachute. "Hardy bugs" kept showing up, including one whose spores lived for 6 days at 125 °C. The launch date had to be just right for slinging a shot through the heavens to intercept a planet in conjunction. Worst of all, the instruments were unprecedented in design, infinite in complexity, and strictly limited in size and weight. In engineers' terms, they cost a million dollars per pound; a compacted 20-kilogram mass of electronic and chemical gadgetry whose price made crown jewels look like dime-store baubles. One of the experiments is called "labeled release". It will incubate a pinch of Martian soil, moistened with water containing radioactively tagged nutrients (formate, glycine, DL alanine, DL lactate and glycolicic acid)

Viking gets ready

from Thomas H. Jukes

for two weeks at 6°–14 °C, and any emitted gas will be monitored for metabolically-produced radioactivity.

The second is "pyrolytic release", based on the idea that photosynthetic fixation of carbon dioxide, and possibly carbon monoxide, should take place biologically under Martian conditions. The surface sample will be exposed to "artificial sunlight" from a xenon lamp for several days in an atmosphere containing $^{14}CO_2$ and a little ^{14}CO. The soil will then be heated to 600 °C to destroy organic compounds resulting from photosynthesis and the emitted gases will be measured for radioactivity. The experiment is designed also to detect dark fixation of $^{14}CO_2$ and ^{14}CO. This experiment is specifically oriented towards Martian organisms that may differ from terrestrial ones in being intolerant of water or "terrestrial nutrients". The third experiment is named "gas exchange" but is often called "the chicken soup experiment" because it frankly seeks to woo Martian bugs with a rich, non-radioactive meal containing amino acids, vitamins and cofactors, salts and other nutrients, from kitchens on the Earth. The soil sample is moistened with the culture medium, and the atmosphere in the chamber, mostly helium, is periodically analysed by gas chromatography to see if gases such as methane and CO_2 are emitted.

At the meeting on June 17, the engineers from Thompson-Ramo-Wooldridge and Martin-Marietta appropriately handed us a glossary of 80 acronyms to help us follow their talks. The mood was one of relief, and guarded optimism. All three of the experimental instruments, miraculously, had come into working order at the last minute. The Viking Biology package, in duplicate, had been loaded into two spacecraft at the Kennedy Space Center in Florida. All that now remains is that the instruments should survive the launches on August 11 and 21, the eleven-month, 450-million-mile journey, and the "soft" landings through the thin (5 millibars) CO_2 atmosphere of Mars in July 1976.

After that, perhaps, the faintly-whispered signals will tell us what is happening; not only in the biology package but in the colour cameras, the water detector, the infra-red thermal mapper, the gas-chromatograph-mass-spectrometer, the X-ray fluorescence spectrometer, the seismometer and the weather station. But a main worry is: if the signals next year say that life may be present, will people believe the message?

international news

US puts energy plans in several baskets

by Colin Norman, Washington

Seamans: laying the groundwork.

REPORTS, analyses, blueprints and predictions on energy policy have been pouring out of government agencies in the United States at such a rate during the past years or so that they now often raise little more than a flicker of public interest before being confined to the bookshelves to gather dust. But a report published last week by the Energy Research and Development Administration (ERDA) has attracted considerable attention, and rightly so.

The first broad statement on energy policy to emerge from ERDA since the agency was established in January, the report reflects an important change of priority among long range energy programmes. Specifically, ERDA recommends that more emphasis should be placed on solar energy and thermonuclear fusion, and less on the liquid metal fast breeder reactor (LMFBR), for meeting energy needs towards the end of the twentieth century and thereafter.

Moreover, ERDA has recommended that funding for a variety of non-nuclear programmes, such as the production of synthetic petroleum and natural gas from coal and the development of technology for exploiting geothermal energy, should be increased immediately, while the nuclear programme should be revamped to give more support to research and development on such items as reactor safety, safeguards and the disposal of radioactive wastes.

Described by Dr Robert C. Seamans Jr, the Administrator of ERDA as "laying the groundwork" for energy research and development planning, the report also tacitly abandons the Project Independence goal of reducing oil imports to zero by 1985 (a goal which has long been considered unrealistic in any case). Instead, the report suggests that the United States is unlikely to become self-sufficient in energy before about 1995, unless there is a significant, and unexpected, change in the American way of life.

The report begins by noting that the United States now relies most on the least plentiful domestic energy resources to meet its burgeoning energy requirements. Petroleum and natural gas account for nearly 75% of total energy consumption, yet the Department of the Interior and a committee of the National Academy of Sciences recently suggested that domestic oil and gas supplies are likely to dry up in

about 35 years. Consequently, a switch must be made to other energy sources as swiftly as possible, but Seamans pointed out last week that previous transitions to new energy sources—from wood to coal in the nineteenth century and from coal to oil and gas since 1900—have taken about 60 years to complete. It is clear, he said, that "we don't have 60 years to transfer another energy source" this time.

First, however, a word about what the report is not. "What you will find here is not an instant remedy for energy problems", Seamans said, "nor can it be looked at as an exact blueprint" because priorities will inevitably change as research and development uncovers problems and opportunities in exploiting new technologies. Rather, it is an assessment of present priorities in energy research and development, and ERDA will update the report each year.

The report also makes no explicit projection of energy demand; instead, it outlines the steps which seem necessary to meet whatever demand arises. That approach, it should be pointed out, ignores such considerations as whether it would be better to reduce energy demand rather than open up new resources—a consideration which many see as the crucial question in energy policy for the United States. The report simply states that energy policy should "provide for future needs so that future life styles remain a matter of choice and are not limited by the unavailability of energy".

The conventional wisdom in government energy planning has essentially been that increased use of coal will help bridge the gap between supply and demand of energy in the short term, and that nuclear power will gradually take over from oil and gas for electricity generation in the longer term. The ERDA report certainly does not abandon that view of things, but it suggests that a much greater role should be played by such exotic energy resources as geothermal energy and solar power. It offers a set of recommendations to help increase domestic energy supplies in the near term (between now and 1985), the mid-term (1985 to 2000) and the long term (early in the twenty-first century).

● For the near term, the report suggests that highest priority should be given to efforts to expand direct use of coal, to increase the proportion of electricity generated by light water reactors, and to enhance the recovery of oil and gas from new and existing deposits. Equally high priority should be given to energy conservation by increasing the efficiency of transportation, improving the insulation of buildings and extracting energy from waste materials.

Some changes of emphasis are needed in existing research and development programmes to help achieve those goals, ERDA suggests. Most important, the report recommends that some money should be taken out of the budget for the LMFBR programme and used instead to help improve the safety and reliability of light water reactors, and to develop safe methods for disposing of radioactive wastes. Research and development aimed at mitigating the environmental impact of coal burning should also receive more attention, the report suggests.

● For the mid-term, ERDA suggests that highest priority should be given

to the development of technologies for producing synthetic petroleum and natural gas from coal, and extracting oil from shale. President Ford announced in January that the Administration has set a target of producing 1 million barrels of synthetic petroleum by 1985, a goal which ERDA says can be achieved only if joint government–industry arrangements can be worked out to ensure that new technologies are swiftly taken up for commercial production. The report also recommends that research and development on *in situ* methods of extracting gas from coal and oil from shale should be stepped up because such methods would cause less environmental destruction and require less water. Equally high priority should be given to increasing the use of geothermal energy for electricity production, and the use of solar energy for heating and cooling buildings. Those resources "promise a significant impact" for the mid-term and beyond, ERDA suggests, but they are at present under-used and under-funded.

● It is in the assessment of priorities for the long term, however, that the report recommends the most significant policy changes. ERDA suggests that the LMFBR programme, the nuclear fusion programme and the develop-

ment of technologies for generating electricity from solar energy should be accorded equal priority.

For several years, the LMFBR programme has enjoyed pride of place as the single most expensive energy research and development effort supported by the federal government. The goal was to have a demonstration reactor in operation by 1980, to introduce the reactor commercially in the late 1980s, and to have about 400 individual plants in operation by the year 2000. But the programme has recently run into considerable trouble. The original estimate that the research and development effort would cost $3.3 thousand million has now risen to $10.7 thousand million, the timetable has slipped, and the programme has met with public concern over the adequacy of safeguards to guard against the theft of plutonium, and fears about the toxicity of plutonium. Because of such problems, ERDA believes that it would be foolish for the United States to place all its eggs in the breeder basket, and it is recommending that solar technologies and fusion be accorded equally high priority.

But that does not mean that ERDA has abandoned the breeder project. Last week, in a seperate statement, Seamans announced that ERDA will

publish an updated environmental impact statement on the LMFBR programme in about three months' time. The objective, Seamans said, will be to press ahead as rapidly as possible with the research and development effort. Once that phase is completed, the government will be in a better position to assess the environmental and safety aspects of the LMFBR before giving the green light to commercial production of electricity from the reactor, Seamans said. "There is no presently available or prudent alternative to this course of action," he believes.

Nevertheless, because of a number of factors, ERDA has decided that construction of the first LMFBR demonstration plant, to be built near Oak Ridge in Tennessee, will not begin until late next year, which will put it another year behind schedule. Consequently, Seamans has suggested that Congress should reduce the LMFBR budget for this year by $60 million and transfer some of those funds to other parts of the nuclear programme.

In order to carry out the recommendations outlined in its report, ERDA has suggested that Congress should increase its budget for various non-nuclear programmes by $143 million for this fiscal year (which began on July 1). The budgets for fusion and solar energy should be increased by $38 million and $19 million respectively, ERDA suggests, while research and development on fossil fuels, geothermal energy, conservation and such advanced energy systems as magnetohydrodynamics should also receive substantial increases.

The requests will certainly not fall on deaf ears. In fact, Congress will probably be even more generous towards some programmes than ERDA wants it to be. Last month, the House of Representatives passed a budget bill for ERDA which would add $158 million to ERDA's budget request for non-nuclear energy programmes, including an additional $43 million for solar energy. The bill has yet to be passed by the Senate, but similar action is anticipated there.

Finally, Seamans noted during his press conference that often "people say, 'well, we ought to be able to solve this problem. After all, we got a man to the Moon in 10 years' ". but he pointed out that "It is one thing to carry out the development and take a relatively small number of astronauts on highly experimental type missions. It is another thing to put into being in this country an energy delivery system. an energy conservation system that will satisfy the needs of over 200 million people". Seamans was Deputy Director of NASA during much of the Apollo programme. His new job will clearly be more challenging. □

SUPPORT of basic research in the United States will decline by about 8% in 1975, largely because of inflation, according to a report published by the National Science Foundation (NSF). The foundation calculates that government, industry and non-profit institutions will provide between them about $4,100 million for basic research this year, an increase of about 2% over last year's expenditures but an insufficient amount to keep pace with an inflation rate of 10–11%.

Overall, however, the picture does not look too depressing, and it is certainly much better than in many other countries where inflation rates are nearer 20–30%. The NSF calculates that total spending on basic research, applied research and development will climb to about $34.3 thousand million in 1975, which is an increase of 7% (or a decline of 3% in purchasing power). The development end of the research and development spectrum will fare best, reflecting the increasing support of energy programmes and the rapid increase in outlay on the space shuttle. Moreover, for the first time, industry is expected to spend as much on development as the federal government—about $11 thousand million each.

The decline in real support for basic research will reduce the purchasing power of the research budget to about the same as it was in 1969, and it follows several years of essentially no growth. Although the NSF does not break down the budget between fields, it suggests that outlays on military and space research and development will account for a slightly smaller share of the total— about 36%, compared to about 50% in the mid-1960s. Outlays in those two areas are expected to be a mere $12.3 thousand million in 1975.

The analysis is based partly on the Administration's budget request, which was submitted to Congress in February. Although Congress has yet to complete action on any major appropriations bill (even though the fiscal year has already started) the indications are that it will increase the total federal outlays for applied research and development while reducing expenditure on basic research even further. Last month, for example, the House of Representatives deleted some $44 million from the NSF's budget, but increased the applied research budgets of the Energy Research and Development Administration and the National Institutes of Health. The Senate is expected to follow suit.

THE inaugural meeting of the World Food Council was in danger of breaking down in Rome last week after delegates of the developing countries had expressed dissatisfaction with the draft final report prepared by the secretariat. A major row blew up as the secretariat was |accused of uncooperativeness and inefficiency, among suggestions from delegates that the Council was dominated by 'imperialistic and colonial forces.'

"Possibly the best thing that could have happened" is how a senior FAO staff member described the row that brought the WFC meeting into the headlines. Just what sparked it off is not clear. One factor was certainly the frustration of delegates—among whom were ministers from some 30 countries—at the inadequate preparation for the meeting, and the inefficiency and tactlessness with which it was handled. Another was probably the feeling among the Third World countries that the United States was trying to bulldoze the meeting into accepting its view of how to deal with world food. In any event, a meeting which, after a week's argument, finds it necessary to appoint a working party to decide its own rules of procedure, and accepts a declaration charging its president with convening a further session "within a reasonable period" cannot be said to have helped put a single spoonful of rice into the mouth of any one of the world's hungry millions.

In the eyes of many people, there is little need for a another new secretariat to operate a World Food Council, but if it must be set up, it should not draw something like half its top staff from the United States—an unnecessarily tactless way of reminding the hungry countries who they depend on for extra food. One thing that has to be clearly seen is that responsibility for the recent farce in Rome rests not with the impatient delegates of the Third World, nor with their exasperated opposite numbers from the rich countries, nor with the FAO, but squarely on the shoulders of the UN in New York. Coming as it does under UN, the new World Food Council is seen as a political body, and one that, as another senior FAO man put it, "has nothing to do with the old, endemic, stratified, perennial and above all, undramatic, world food problem. You can't go on dealing with a long term problem only when events (such as the Sahel disaster) force the politicians to notice it."

Another important factor in this messy situation is the open and long standing disagreement between the FAO, the agency responsible for world food, and UN headquarters in New

York, which is concerned with the politics and economics of the food problem, but hardly at all, it sometimes seems, with the fate of the hungry millions. At the World Food Conference, also convened by the UN and held in Rome last November, it almost seemed that the FAO was about to be dismembered, with some at least of its functions being taken over by the UN —presumably on the grounds that after 30 years of existence, the agency has still failed to prevent people from being underfed, something it was not set up to do in the first place. It was in Rome that Dr Kissinger, in one of the less fortunate pronouncements of his career, stated that the world food prob-

Facing the facts about food

from Peter Collins, Geneva

lem could be solved in 10 years. What is even more unfortunate is that this was accepted by the UN as a basis for the policy of the proposed World Food Council, to the dismay not only of the FAO but also of the many people inside and outside the UN system who are aware that neither the past performance, nor the current statistics, nor the future promise of the world community justified such a statement.

Here at least the record was set straight by Dr Adekke Boerma, the FAO's Director-General, in his unscheduled speech to the recent Rome meeting. He stated bluntly that the professed aims of the World Food Conference "cannot be brought about within the next 10 years." Nor would he like to say when even the target of 3.6% a year for increased food production could be met. Last week, at the Geneva meeting of the UN's Economic and Social Council, Dr Boerma returned to the attack. Pointing out that "bad weather conditions can hardly be blamed" for the long term lag in agricultural production, he analysed the major constraints both within the developing countries, and in the world community as a whole, which have perpetuated the dismal performance of world agriculture for the past 25 years. Many of these are longstanding, highly intractable problems—lack of fertile land and water resources, absence of suitable technology for the many millions of largely illiterate peasant farmers, land tenure systems which militate against increased production by removing all personal incentives, the whole inadequate rural infrastructure in the developing countries. But much of the blame lies outside these countries. "The attitudes in developed countries

tries which largely control the conditions of international trade, with the exception of oil, provide other constraints. International agricultural adjustment and a more rational world, division of labour are needed to increase employment in developing countries as well as their export earnings," said Dr Boerma.

It was worth noting, he added, not only that the international development assistance had conspicuously failed to meet the targets of the Second Development Decade, but also that less than 10% of official development assistance was allocated to agriculture. Calling for food aid to be "deliberately planned as an integral part of world food policy", he reminded the developing countries that "food aid is a bridging measure that will tide them over until their efforts to increase their agricultural growth rate begin to pay off." And finally, the key was to find and implement the means of increasing the purchasing power of the world's peasantry, for the biggest constraint of all is poverty.

Boerma pointed out that, in spite of prospects for a good crop for 1975-76, world food stock would remain dangerously low, and the "most seriously affected" countries would still face a food gap of between 15 and 20 million tons for 1975–76. What is needed is a vast cooperative effort to bring about "general economic and social development on a massive scale that will enable the legions of the poor ... to earn a decent livelihood so that they can buy the food they need."

Dr Boerma remains unconvinced that the World Food Council, at least as at present planned, can bring about these aims in the short (10 year) term. But while he was speaking in Geneva, the first meeting to try to set up an Agricultural Development Fund was going on in Rome. This may prove to be the one solid achievement of last year's World Food Conference. The debate lies between the Arab, oil-producing countries, who have shown themselves willing to put up their share of the cash, the United States, and the EEC. It is the last of these, notably West Germany, who have been dragging their feet, with Britain in the perhaps unusual role of trying to persuade her partners to spend more. At the recent Rome meeting, it was Britain that set the pace with a pledge of a further $15 million above her already large contribution to the international fertiliser supply scheme. This is an essential part of the effort to help the needy countries produce more of their own food, which, as everyone agrees, is the only way the world food problem can be solved in the long term.

Crowther-Hunt's proposals

SIR,—Your leading article (May 29) outlines proposals which Lord Crowther-Hunt anticipates the academic community will eventually endorse. He wants the opinion of university teachers in order to support his own case, but any alteration in the role of universities in Britain will of necessity require discussion among teachers, employers and students.

Lord Crowther-Hunt should ask his colleagues in the government, 'did they suffer or did they benefit from a university education?'

It is facile to quote a figure of 400,000 in full-time tertiary education and the commitment to increase this number to 640,000 by 1981. Has anyone gauged opinions among students, because it would seem that from an economic standpoint there is a distinct disadvantage in pursuing tertiary education. As one graduating student said to me, "I feel cheated because at school I was told that job opportunities would increase enormously if I had a degree and now four years later the choice of jobs is very limited".

In my own department, where some 65–70% of young graduates have obtained a higher degree, we see trained personnel leaving the country because of lack of opportunity. Although this provides some academic benefit to our department, it is almost impossible for these people to return to the UK. I know of two instances where our graduates could only afford to return if they were given professorships, because of the low salary scales in Britain.

In 1967 the Committee of Vice-Chancellors and Principals carried out a survey of the hours worked by university staff. An example of the hours/week was 54 for a vacational period, 63 for term-time and 80 for an examination period. University teachers do not receive remuneration for the vast amount of work which they take home. I wonder how many trade unions would tolerate a situation in which conditions of service are so loosely defined. Recently, Dr Alex Comfort commented on the situation in one research institute where "geriatric cases some of them, drawing fat salaries for years and doing absolutely nothing" created an impression of idleness among all the staff. Such situations are not unknown in universities and could be controlled

with a scheme of voluntary retirement before the official retiring age.

It might be considered relevant to design courses to meet the needs of the country but it would surely follow that relevant employment with a career structure should be available at the end of the course.

In 1968, however, a learned society formed a temporary committee for liaison between employers and teachers. The conflicting demands of employers were such that it was considered to be almost impossible to design a completely acceptable course for all employers. One must realise, therefore, that the demands of the employer should not dominate the discussion.

The increase in student–staff ratios from 8.4 : 1 to 10–11 : 1 is irrelevant when considering increased productivity and the number of staff to be retained in universities. The student–staff ratio or FTE (formal teaching equivalent) does not include the requirement for repetitive teaching to small aliquots of one large class, that is, the staff time involved to complete one course. I would suggest that increased expansion and productivity, if it is desirable, is a function of staff–student ratios, staff-time per student, space to accommodate larger classes, job opportunities, salaries, rationalisation of university courses, the needs of the country and continued investment in universities.

The last proposal to examine the balance between teaching and research in universities is very important. In view of the anticipated increase in time spent on teaching it seems that Lord Crowther-Hunt is proposing a reduction in research programmes. The subsequent effects of such a move would be disastrous. The move would not immediately affect the quality of teaching but would eventually affect the quality of universities. This would severely affect student populations and bright students would flee. There is a school of opinion which believes that the present government equates private education in the secondary field with universities in the tertiary field of education. Before Lord Crowther-Hunt and his colleagues in the Department of Education and Science run the bulldozer over the universities and produce comprehensive tertiary education they should consider the consequences.

English and editorial boards

SIR,—Dr M. Charles (May 8) wonders what members of the editorial board of certain journals do, apart from collecting an annual fee and refereeing a paper or two. Speaking as a literary hack whose job it is to edit such papers so as to give them a veneer of literary and scientific competence, I question whether these august editorial names ever referee any of the papers submitted because (a) they would not be able to understand some of the appallingly ill-written stuff, (b) if they could understand it they would realise that much of it is not worth publishing.

Papers submitted in English by authors with another mother tongue are certainly often unintelligible, but it must be confessed that some native efforts from certain of our English universities and technical colleges run them pretty close. This is due to the recent proliferation of such institutes, with the result that anyone who is not actually moronic can now qualify for higher education. The effect is that people who in saner times would be happily and usefully employed behind the counter of the local grocer's now feel impelled to give the world the fruits of their intellectual labours.

J. C. ANDREWES
Cambridge, UK

Not worried

SIR,—I really rubbed my eyes at your contributor John Hall's statement that in Cambridge "The number taking chemistry is so small that professors are starting to worry about the security of their salaries .. " (*Nature*, May 22). The facts are precisely the reverse. The number of third year students opting for chemistry at Cambridge has risen steadily over the past three years and there is already a firm indication of 70 for next year's numbers (the final figure is usually above this initial assessment). The postgraduate situation here shows a similar robust health, particularly in organic chemistry, where it is clear from the shoal of applications that every available place will be filled. I can therefore reassure John Hall that he need not rattle a collecting box for Cambridge chemistry professors just yet.

news and views

ALMOST six years have passed since the first manned landing and the return of lunar soils and rocks to the Earth. Six manned American and two automated Soviet samplings have amassed some hundreds of kilograms of lunar samples, many thousands of pictures and vast collections of instrumental data The rocks and soils have been photographed, microphotographed, measured for almost every conceivable physical property, picked over, separated, melted, dissolved, and analysed for elements and minerals. What do we now know about the Moon after this first detailed look at another body in the Solar System, using combined space technology and laboratory analyses?

The meeting at the Royal Society attempted to answer this question, but inevitably it has raised many others.

History of the Moon
One major theme was the lunar time scale. An initial Moon-wide melting around 4.6 Gyr to 4.4 Gyr ago, to an undetermined depth, seems to have led to extensive chemical differentiation, producing the aluminium-rich lunar highlands underlain by a mantle rich in iron and magnesium An intense asteroidal and meteorite bombardment then produced the dense cratering of the highlands and ended rather abruptly at 3.9 Gyr ago, possibly during a final burst of increased activity following some undetermined 'cataclysmic' event. The next phase from 3.9 Gyr to 3 2 Gyr consisted of partial melting of the lunar mantle at depth, producing volcanic lavas which spread out as a thin sheet over the rubble, filling the major impact basins. During the last 3 2 Gyr the lunar lithosphere has been too thick and impenetrable to permit these extrusions to continue in all but a minor way Events in this period have been mainly restricted to occasional large impacts, producing craters such as Copernicus and Tycho, and a steady infall of minor amounts of meteoritic debris.

Although this broad outline is widely accepted a number of fundamental difficulties remain. J. Wasserburg of Caltech raised a number of questions in connection with the early differentiations and the later generation of mare basalts. Was the initial differentiation largely complete by 4.4 Gyr ago or did it extend in a continuous way down to the time of the mare basalt flows? The isotopic data

Probing the Moon

from Correspondents

The Royal Society held a discussion meeting on 9–12 June entitled "The Moon—A New Appraisal from Space Missions and Laboratory Analyses"

appear to favour the former view. Refined uranium–lead data indicate that the iron-rich mantle, from which the mare basalts were later generated, was formed 4.4 Gyr ago. This being the case, where in the Moon are the lead daughter products which were generated from 4.6 to 4.4 Gyr? The mechanism for remelting the mantle at later times to produce the mare basalts is also a major unsolved problem, and what is the significance of the apparent absence of mare basalt clasts from the highland breccias? J. Geiss (University of Berne) stressed the mounting evidence from Apollo 11 samples that at least for this site chemically distinct basalt extrusions occurred over a period of 300 Myr. The crater counts in this area of the Moon by G. Neukum (Max-Planck Institute, Heidelberg) support this view

A current controversy over the precise significance of the $^{40}Ar-^{39}Ar$ ages of highland breccias was aired by several speakers G. Turner (University of Sheffield) interpreted the ages of the Massif boulders from Apollo 17 as indicating the time of the Serenitatis basin impact, a significant marker in the lunar stratigraphic sequence. This view was supported by trace element arguments by E. Anders (University of Chicago). In contrast, O. Schaeffer (State University of New York, Stony Brook) stressed arguments supporting a significantly older age of 4.28 Gyr for Serenitatis, and P. Horn (Max-Planck Institute, Heidelberg) emphasised the importance of smaller events in resetting the argon clock. The various interpretations of the highland ages carry important implications for the crater counts made by and discussed by G Neukum An old age for Serenitatis would probably be consistent with a steadily decreasing cratering rate for the early highland bombardment whereas the younger age

seems to require a late stage cataclysm, or dramatically increased cratering rate, at 4.0 Gyr.

Lunar petrology
The basalt lavas that flooded the mare basins from about 3.9 to 3.2 Gyr ago show evidence for a genetic relationship with both the feldspathic crust and the ultramafic mantle. Petrologists and geochemists spoke for and against the Taylor–Jakes model of two-stage melting to explain these relationships. G. M. Brown (University of Durham) showed how the model could explain the 4.6 Gyr model ages of the basalts, the europium anomalies, and the contrasted crystallisation ages and generation depths of the high- and low-titanium basalts, if a terrestrial-type cumulate model involving convection is examined. Some deficiences in the model were exposed by S. Kessen (State University of New York, Stony Brook) who indicated the need for a titanium-rich magma just below the crust (65 km) and the role of basalt contamination by crustal rocks. A. E. Ringwood (University of Canberra) doubted that the Moon was totally melted deeper than about 200 km early in its history (as required by the two-stage melting model), and argued for a lunar mantle similar in composition and density to the Earth's. Also that existing models for the total Moon composition were too rich in CaO and Al_2O_3 to give mare basalts by partial melting M. J. O'Hara (University of Edinburgh) referred to his experimental evidence in support of two revisions of lunar basalt origins. First, crystal sorting within the surface lava flows precludes the use of hand-specimens to predict the nature of the lunar interior Second, the existence of highly feldspathic liquids is evidence for the original presence of water in lunar highland magmas. These discussions and the restraints imposed by the lithospheric rigidity history and crustal-thickness variation, from gravity determinations by S. J. Sjögren (California Institute of Technology), indicated that the whole question of the Moon's thermal history and magma generation is still an open one

Lunar magnetism
The study of magnetic properties of lunar samples now seems to be geared to the most important goal of estimating the intensity of the ancient mag-

netic field. D. W. Collinson, A. Stephenson and S. K. Runcorn (University of Newcastle) presented data suggesting a trend of decreasing field, from 1.3 Gauss at 4 Gyr to about 0.05 Gauss at 3.2 Gyr, but there was little sign of any concurrence with this idea from the other speakers. M. Fuller (University of California, Santa Barbara) showed palaeointensity results in which there was no discernible trend although these were based on an approximate method. The interpretation of lunar magnetic anomalies is also at a very interesting stage; D. Strangway (University of Toronto) showed that some anomalies can be accounted for by a layer of horizontally magnetised material in the floor of some craters. On a more global scale P. J. Coleman (University of California, Los Angeles) showed that satellite observations give the upper limit to the lunar dipole moment as about 10^{19} Gauss cm³. This low value virtually rules out the original magnetisation of surface rocks in a uniform external field as shown by Runcorn and indicates an ancient field of internal origin—a very important contraint on the lunar history models.

Microscale processes

Micrometeorite impact is responsible for the observed particle size distribution within the soil and the formation of secondary particles (glassy welded aggregates), and may be the major mechanism of lateral transport of dust grains. But there was controversy as to whether micrometeorite particles travelling normally to the plane of the ecliptic have the same size distribution as particles in the plane of the ecliptic and as to whether the micrometeorite flux has varied with time. No evidence has been found for the deposition of impact-produced material although in μm-size craters up to 50% of the material from the projectile is retained

The major erosional effect at the Angstrom level is due to sputtering by the solar wind and estimates of the rate of mass wastage generally are in good agreement. The chemical changes which can be effected by solar proton bombardment were discussed at length by C. T. Pillinger (University of Bristol), R. M. Housley (North American Rockwell) and T. Gold (Cornell University), particularly the formation of free iron which has implications for carbon chemistry, magnetic properties and the albedo of the soil. Although rare gas systematics of the soils are now fairly well understood there is still no completely adequate explanation of the excess of ⁴⁰Ar found, as pointed out by P. Signer (Swiss Federal Institute, Zurich). Chemical elements such as carbon and nitrogen have been accepted as indicators of

solar wind bombardment. T. Kirsten (Max-Planck Institute, Heidelberg) reported that nitrogen seems to be the more effectively retained element since N/C ratios for the lunar soil are in excess of those measured for the Sun.

The conference closed with a look into the future by Noel Hinners, head of NASA's planetary programme He pointed out that lunar research has proved to be an excellent prototype for exploration of the Solar System. The Moon also serves as a proving ground for the necessary space technology. Further manned expeditions are unlikely before the late 1980s when lunar bases will probably be set up. Meanwhile, around 80% of the returned lunar samples still await detailed analysis. Plans are going ahead for an unmanned lunar polar orbiter which would carry out detailed Moon-wide surveys of a number of important elements and physical phenomena. Several UK scientists are hoping to participate in this project.

Collaborating T and B cells

from Fritz H. Bach

RECOGNITION of antigen by lymphocytes of the immune system is the basis of the exquisite specificity of response characterising that arm of our bodily defence against foreign invaders. With the realisation that lymphocytes can be grossly divided into two classes, T (thymus dependent) and B (bone marrow derived) cells, and that both of these show great specificity in their response patterns, it was assumed by many that T cells must express specificity in a way similar to B cells. Our understanding that B cells carry immunoglobulins on their surfaces which are used as antigen recognition sites, or receptors, led logically to the possibility that T cells use the same set of molecules as receptors. This assumption has, during the last few years, been queried by many; now again there is immense controversy over whether T cells, like B cells, use immunoglobulins as their membrane receptors.

A possible clue relating to the genetic control of T-cell receptors came from the finding that genes of the major histocompatibility complex (MHC) control immune responsiveness to specific antigens. These immune response, or *Ir*, genes seemed to be expressed in T cells. Later experiments demonstrated that *Ir* genes could also be expressed in B cells.

With the appreciation of the distinction between T and B cells came evidence that these two cell types cooperate in antibody production by B cells—a phenomenon referred to as

T–B cell collaboration. For what is known as a T-dependent antigen, both T and B cells must recognise the antigen; the B-cell response (antibody production) is dependent on help from the T cell The first suggestion that this T-cell help for B cells may come by way of a humoral factor presumably secreted by T cells came from work of Dutton and coworkers.

These two apparently separate lines of investigation involving T-cell factor(s) in T–B collaboration and the genetic control of the immune response were brought together by the observation in several laboratories that the T-cell product which facilitated B-cell response carried antigenic specificities determined by MHC genes; further that these genes mapped genetically with the *Ir* genes. The situation is best analysed in mouse. The *I* region of *H-2*, the MHC in mouse, includes the *Ir* loci; in addition antisera have been raised against *I* region products defining Ia (*I* region associated) antigens. It is with the anti-Ia antisera that the T cell product reacts. Since in the experimental systems of at least some laboratories the T-cell factor has antigenic specificity, it becomes a prime candidate for the T cell receptor. That the factor is not immunoglobulin is supported by several lines of investigation detailed by Munro and Taussig. (this issue of *Nature,* page 103).

The perplexing finding that *Ir* gene control is sometimes expressed in T cells and other times in B cells now seems to have a logical explanation. A number of groups (for references see the article by Munro and Taussig) now have evidence that two separate *Ir* genes linked to *H-2* are involved in the control of a given immune response. One of the two genes controls the ability of the T cell to produce the factor; the other appears to control a 'receptor' on the B cell which combines with the secreted T cell factor. Whereas the T cell factor clearly carries Ia antigenic determinant(s), the receptor on the B cell has so far only been shown to be associated with antigens defined by sera against both the Ia antigens and other *H-2* determinants although Munro and Taussig reasonably argue that the active moieties in these sera may also be anti-Ia.

The evidence provided by these authors and others is elegant in the synthesis they provide for the dual genetic control, the elucidation of the dichotomy between control of factor production versus a defect in factor acceptance and in the implications of these findings for cell collaboration Although at least to some their model may seem awkward in certain minor details, especially in their attempt to explain the specificity of response

defect by limiting the responsiveness toward any given antigen to only some 'classes' of T cell receptors, it stimulates not only further experimental protocols in T–B collaboration but in several other systems. The importance of the Munro–Taussig work, with its demonstration of antigen specificity of the T-cell factor, the individual *Ir* control of T cell factor and B cell receptor for that factor, thus lies not only in the advance this provides for cellular immunology but also in the broader applicability of the model for cell cooperation which can now be studied at the molecular level.

In addition the two MHC *Ir* gene control of immune responsiveness is exciting to the geneticist. The MHC has often been referred to as a supergene as described by Fisher, that is, a group of linked genes that govern biologically interactive processes. During the past few years we have seen the elucidation of at least one such interacting system within the MHC where different antigens controlled by separate MHC genes (the SD and LD determinants) differentially activate

two separate populations of interacting T cells (T–T collaboration); an interaction which leads to the effective development of cytotoxic T lymphocytes. Munro and Taussig in fact speculate that their model for T–B collaboration may apply to T–T interactions. It may be that the antigens to which the separate T cell populations respond can also function as receptors (which may really be their major role) and that an even closer parallel than that envisioned by some will emerge between the LD–SD interaction and the T–B collaborating system.

Thus whereas many questions of key import remain (such as the possible participation of the variable part of the immunoglobulin molecule as a part of the T cell receptor, the question whether there are classes of T cell receptors which explain the specificity restrictions, and many others) the results and models generated by this group and others working in the same area are enormously exciting and provide a focus for the bringing together of several diverse experimental systems related to MHC genes.

Protein folding pathfinders

from Barry Robson

TRYING to discover how a globular protein folds up into its unique, biologically active conformation is not a task for the faint-hearted. The conformation of a protein is determined by hundreds of rotatable bonds, and hence its conformational energy can be described mathematically as a continuous surface with hundreds of dimensions. Through the hills and valleys of this conformational energy surface the molecule must weave its way in search of that single valley which represents the stable, biologically active conformation. A number of recent publications, some relating to experimental observations on folding proteins, and some to computer simulations of the folding process, give considerable insight into the most challenging and contentious aspects of the problem.

Pancreatic trypsin inhibitor is a relatively small protein of known three-dimensional structure and continues to be a popular model system. Creighton (*J. molec. Biol.*, **95**, 167; 1975) continues his experimental investigation of the folding of this molecule, again forcing the formation of disulphide bridges at selected intervals of time in order to covalently cross-link the backbone chain of the molecule and so trap intermediate conformational species. In this paper he directs his attention to the analysis of those intermediate species which have two such links, and observes that the various elements of the biologically active conformation must be assembled in a definite sequence. His findings therefore support the increasingly held belief that there is a unique and obligatory pathway for folding, and that the biologically active conformation is marked not so much by its own stability as the stability of the pathway leading to it.

Creighton's emphasis on a specific folding pathway seems at first glance inconsistent with his additional discovery that the protein in the early stages of folding has considerable conformational freedom in which many different conformations are built up. However, the initial population of the disordered, fully unfolded state contains an enormous variety of conformations which must be funnelled together into the first obligatory step at the start of the pathway proper. The initial intermediates therefore resemble the routes taken by the participants on their way to the official meeting place at the start of a sponsored walk.

Events at the beginning of the folding pathway have also been recently examined in ribonuclease A. Garel and Baldwin (*J. molec. Biol.*, **94**, 611; 1975)

New view of magnetic changes

from Peter J. Smith

THE magnetic field at the Earth's surface generally deviates from the north–south direction (declination), certain components of the field drift slowly westwards (secular variation), and from time to time the main field changes its orientation by 180° (field reversal). But although these phenomena are observable, directly or indirectly, their causes remain obscure. Declination, for example, is generally explained in terms of non-dipole components; but insofar as the origins of the non-dipole fields are uncertain, this merely shifts the obscurity one stage further along. And although it is usual to invoke eddy currents near the edge of the core, field perturbations which trigger greater changes in a homogeneous dynamo, and so on, such 'explanations' are generally intractable to rigorous analysis.

In sharp contrast, Steenbeck and Helmis (*Geophys. J*, **41**, 237; 1975) have now put forward—tentatively—a quite different hypothesis which is not only amenable to mathematical treatment but is also able to link declination, secular variation and field reversal within a common theoretical development. The theory relates strictly to a simple model of a particular form of gyroscope—a rigid body free to rotate within a rotating hollow sphere and weakly

coupled to the sphere by isotropic friction. Steenbeck and Helmis propose, however, that the analysis may also be applicable to the Earth, with the solid core representing the rigid body of the theory.

In Earth terms, the theory predicts that varying irregularities in the magnetic field are a necessary consequence of a slow rotation of the solid core (gyroscope)—a rotation which is both possible and likely. The interaction between field and core arises basically because, being electrically conducting, the core should be penetrated by a part of the field which it then carries along. The axis of the core's rotation will lie in the Earth's equatorial plane and will rotate within it, thereby giving a westward drift of varying velocity (although eastward drift could also arise under certain circumstances). But the rotational state producing the drift ultimately becomes unstable; and the solid core then tips over relatively rapidly, possibly initiating a total field reversal.

There are several problems, chief of which is that mass movements in the fluid outer core will lead to friction which is neither weak nor isotropic. But although this may alter the quantitative argument, it should not invalidate the principle.

have shown that the thermally unfolded state of this protein is an equilibrium mixture of at least two species, one which initiates rapid folding and one which initiates slow folding. In an extension of this study (*J. molec. Biol.*, **94**, 621; 1975) the authors confirm and explore a physical difference between these species. Kinetic analysis shows that the fast-folding species is an intermediate on the folding pathway from the slow-folding species, but, unlike most intermediates found in proteins so far, it represents a considerable fraction of the initial unfolded state. Although the initial unfolded state prepared by heat denaturation of the native protein may not resemble an initial state prepared in other ways, the study does highlight the possibility that the unfolded state itself may not be one of homogeneous disorder.

In conjunction with Creighton's view this would suggest a picture in which our sponsored walkers converge on the official starting point not from a wide variety of different home addresses, but from a limited number of densely populated areas.

The relatively small size of pancreatic trypsin inhibitor makes it an equally popular system with those who would simulate protein folding by computer. After all, proteins contain thousands of atoms, while there are very much smaller molecules at which a theoretical chemist would sensibly balk. Even so, Burgess and Scheraga (*Proc. natn. Acad Sci. U.S.A.*, **72**, 1221; 1975) have produced what at first reading appears an uncharacteristically melancholy document demonstrating that by existing algorithms it is impossible to simulate the folding of trypsin inhibitor.

Their conclusion might appear to contrast with that of Levitt and Warshel (*Nature*, **253**, 694; 1975); but it would not be entirely justifiable to compare these conclusions since they relate to two fundamentally different methods with different immediate aims. Whereas the Levitt–Warshel approach is to reduce the complexity of the energy surface by simplifying the representation of a protein molecule, Burgess and Scheraga favour retaining a more realistic representation of a protein while reducing the computing time by other methods. In particular, they favour starting the simulated folding process from conformations which they hope are already fairly close to the biologically active conformation, at least as far as the conformation of each amino acid residue in the protein backbone is concerned. A variety of algorithms for predicting such starting structures already exists, most of them based on statistical analysis of amino acid residues in proteins of known sequence and conformation. Burgess

and Scheraga find all these predictions wanting as practical starting structures because the ambiguities and inaccuracies currently inherent in the algorithms which produced them must lead to major ambiguities and uncertainties concerning the conformation of the protein as a whole.

The theoretician seeking to fold proteins inside the computer therefore seems to face a dilemma of either using a simplified representation of a protein molecule, and so study folding across a possibly unrealistic energy surface, or of using a more realistic representation, and sending the folding process down the wrong pathway. In practice, no one has proposed using only one of these approaches and it is reasonable to expect that the ultimate practical and repeatable method will utilise elements of both. In any case, current understanding of the folding of proteins suggests that the starting configurations considered by Burgess and Scheraga are more than a convenient artifice. Creighton's experimental work supports the idea that fairly early steps in the folding process are restricted to a limited number of pathways by thermodynamically stable intermediates. If predicted starting conformations can be identified with such intermediates then they represent structures which ought to appear early in any realistic folding simulation. Ultimately successful computer programs using statistical prediction algorithms to select starting conformations would then merely resemble elderly sponsored walkers taking advantage of a handicap system which allows them to join the walk at a later stage without sacrificing any sense of communal achievement.

Fortunately, the prediction of suitable starting conformations is only one of the methods by which computing time can be reduced In particular, Hagler and Robson (*Specialist Periodical Reports*, **6**, 207, The Chemical Society, 1975) have reviewed a class of procedures which, by analogy with methods used for solving complex problems in other fields, may be termed 'heuristic'. But they used the term more specifically for procedures which obtain additional information from outside the conformational energy surface. Up till now, such heuristic procedures have generally been confined to the prediction of starting conformations or the imposition of constraints on the possible final folded structures, but recently Nagano and Hasegawa (*J molec. Biol*, **94**, 257; 1975) have made use of a penalty function which applies throughout the simulated folding. This penalty function includes estimates of the interaction between residues far apart in the protein backbone, but brought close together in three dimensional space by the folding of the protein. These

estimates are dependent on the conformation of the interacting residues and were derived by previous tests on proteins of known sequence and conformation The use of penalty functions is in the best tradition of heuristic programming in its widest sense, and will probably prove very useful. But Nagano and Hasegawa caution that "It would be premature to discuss [whether the penalty function as described] is realistic or useful" Clearly this kind of approach is still in its infancy.

Finding the pathways by which proteins fold taxes the ingenuity and resources of experimentalists and theoreticians alike. In order to communicate their ideas, protein folding pathfinders have developed or borrowed concepts and terminology which frequently confound other life scientists. It would be regrettable if this obscured the prevailing pioneering spirit, for what may at this moment in time be a sponsored walk for a protein molecule is an exploration of uncharted territory for the scientist.

Getting more CO$_2$ into food

from Israel Zelitch

'PHOTORESPIRATION' finally became a familiar word to the top Wall Street executives who read their June issues of *Fortune* or *Business Week* magazine. Articles unexpectedly cropped up there describing the potential importance of slowing photorespiration for increasing food production. At the same time about two hundred scientists (a fairly even mixture of plant physiologists, biochemists, plant breeders, and agronomists) gathered in Madison, Wisconsin to attend the Fifth Steenbock Symposium held from June 9 to 11 at the University of Wisconsin

The subject of the symposium was billed as CO$_2$ metabolism and productivity of plants A number of topics relating to photosynthesis and productivity were talked about, but nine of the twenty-five scheduled talks and most of the questions and discussions in the conference hall seemed to deal with the background and latest work on photorespiration. The greatest controversy was generated by the difference in the views expressed by some leading investigators about the biochemical mechanism for the synthesis of glycolic acid, the chemically simple but enigmatic substrate of photorespiration.

The symposium was organised by R H. Burris (University of Wisconsin), whose laboratory published some of the first plant biochemistry relating to glycolic acid in 1949, and C. C. Black (University of Georgia). Talks by crop physiologists and plant breeders were

interspersed with papers of a more biochemical nature.

The programme covered recent progress in C_3-metabolism (species with fast photorespiration and slow net photosynthesis), C_4-metabolism (species with slow photorespiration and fast net photosynthesis), and crassulacean acid metabolism (a combination of C_4- and C_3-biochemistry that occurs mainly in species normally found in arid habitats).

Ribulose diphosphate carboxylase is the enzyme mainly responsible for fixing CO_2 during photosynthesis, the product of the reaction being two molecules of phosphoglyceric acid. W. L Ogren (University of Illinois) and N. E. Tolbert (Michigan State University) presented the evidence that this enzyme has a dual activity since it also catalyses a reaction between the substrate (ribulose diphosphate) and O_2. The products of the 'oxygenase' reaction are phosphoglycolic acid (a precursor of glycolic acid) and phosphoglyceric acid (the same product formed by the carboxylation reaction). Since O_2 competes with CO_2 for the isolated enzyme in a manner reminiscent of the inhibition of CO_2 assimilation by O_2 in leaves (the Warburg effect), they argue that the 'oxygenase' reaction accounts for all of the glycolic acid produced in leaves and hence all of the photorespiration. Ogren, R. G. Jensen (University of Arizona), and R. C. Chollet (duPont Co.) described biochemical schemes containing carbon balances that they stated could account for glycolic acid synthesis and photorespiration. These schemes assume that all of the glycolic acid comes from the 'oxygenase' reaction and that no more than about 20% of the carbon fixed during photosynthesis is released as photorespiratory CO_2.

Jensen added that he thought there might be other biochemical mechanisms for glycolic acid synthesis. A critical listener noted that none of the schemes account for the well documented observation that photorespiration often consumes at least 50%, and not 20%, of the CO_2 fixed during photosynthesis. Another omission seems to be that the stoichiometry of the products of the 'oxygenase' reaction, on which the above schemes depend, has never been presented. A further weakness of the argument is that the rates of glycolic acid formation by the 'oxygenase' activity in normal air with Jensen's lysed chloroplast preparations are only about 10% as fast as rates occurring in leaves.

There was a strong difference of opinion over whether the ratio of the 'oxygenase' to carboxylase activity is a constant. Tolbert showed that certain metabolites, such as ribose 5-phosphate, could inhibit the 'oxygenase' and not

the carboxylase activity and suggested that metabolites could affect the balance between net CO_2 assimilation and photorespiration. C. C. Black stated that this ratio of activities could vary by as much as 10-fold in leaf extracts from different species. During the course of a special discussion session largely devoted to problems relating to the assay of the 'oxygenase' activity, it became apparent that many factors affect the assay including whether or not the enzyme has had prior contact with bicarbonate.

The C_4 crop species (maize, sugarcane, sorghum) generally have much higher rates of net photosynthesis and productivity than the C_3-species. M. D. Hatch (CSIRO, Canberra) further elaborated the hypothesis that these species are able to raise the CO_2 concentration in their leaf bundle sheath cells by transporting malic acid (or other C_4 compounds) into these cells and then decarboxylating it. The resulting higher CO_2 level in the bundle sheath cells inhibits glycolic acid synthesis and photorespiration and promotes a speedup of CO_2 fixation by enzymes of the pentose phosphate cycle. The CO_2, he believes, does not have much of an opportunity to diffuse out because it is fixed so rapidly.

Painstaking cytogenetic work on the results of several generations of crosses between a C_4- and a C_3-species of *Atriplex* was described by O. Björkman (Carnegie Institution, Palo Alto). The hybrids produced, however, had poorer rates of net photosynthsis than either of the parental types, and he concluded that it is extremely unlikely that superior hybrids will be obtained by conventional interspecific crossing.

Plant breeders who are anxious to incorporate superior photosynthesis into their plants in order to obtain higher yields have had many frustrations and misgivings This was clearly illustrated in the talk by D. H. Wallace (Cornell University) who emphasised that there are numerous systems and interactions concerned with plant productivity besides photosynthesis. He argued that changing only one component of the system, such as photosynthesis, would probably not increase the yield say of dry beans A member of the audience pointed out that plant breeders have not yet had the opportunity to move a characteristic such as superior photosynthesis into different genetic backgrounds in order to make a proper evaluation. A listener also remarked that increasing net photosynthesis by raising the CO_2 concentration in a closed system would surely increase the yield of dry beans, and one must therefore assume that if large increases in net photosynthesis could be obtained in normal air it would be similarly beneficial.

Many participants felt that more opportunities such as this symposium should be created to permit research workers from different disciplines to share information about plant productivity. It appeared to me that the world food problem has finally touched many scientists who might previously have been more aloof from problems existing in the real world.

Assembly of regular viruses

from a Correspondent

The Discussion Meeting arranged by A. Klug and P. J. G. Butler (MRC Molecular Biology Laboratory, Cambridge) for the Royal Society on June 18 and 19 was held to review the more recent work on the spontaneous assembly of viruses, with particular reference to the 'regular' viruses.

As a group viruses have been found to have surprisingly few similarities other than those dictated by size, pathogenicity and the available building materials. Constrained to have their hereditary material as some kind of nucleic acid they may have RNA or DNA (but so far not both) in any of many forms, single stranded, double stranded, circular, in several pieces and so on. Not surprisingly the associated coat structures are equally variable, so that the discussion proved to be more of an analysis than a synthesis.

Although the self-assembly of the tobacco mosaic virus has been recognised for twenty years its mechanism is not yet fully understood, as was made clear by K. E. Richards (Institute de Biologie Moleculaire et Cellulaire, Strasbourg) and P. J. G. Butler and D. E. G. Zimmern (both MRC Laboratory of Molecular Biology, Cambridge). A method for finding the 'recognition site' of the viral RNA is the selective coating of its fragments, a method previously employed by J. G. Atabekov (Moscow State University) who yet again was prevented from attending a meeting in this country. Rather unexpectedly, these fragments have been found by Richards and his colleagues to contain the coding sequences for the coat proteins, which are known from other evidence not to be in the recognition site region.

In the case of one of the small spherical viruses, brome mosaic virus, which is held together by hydrogen bonds between carboxyl groups and by protein–RNA interaction, the coat was shown by B. Jacrot (Institut Max Von Laue-Paul Langevin, Grenoble)

to be assembled from protein subunits existing in a metastable state. He also presented data on the protein–RNA locations in this virus from small angle neutron diffraction in D₂O–H₂O mixtures, a technique with considerable potential. The requirement for metastable intermediates was also put forward by J. King (Massachusetts Institute of Technology) to explain the complex but orderly assembly of the tail of the T4 bacteriophage. Several speakers discussed the details of the band assembly of this and other bacteriophages. An interesting sidelight is the re-use of components necessary for the assembly but not incorporated in the mature virus.

Other speakers dealt with various small viruses including the flexuous plant viruses, one of which, potato X virus, has been reassembled *in vitro*, and spherical viruses, like the turnip yellow mosaic virus, the shell of which is stable in the absence of the nucleic acid, does not rely upon carboxyl hydrogen bonding for its stability and has not yet proved completely amenable to efforts to reconstitute it.

Antigen receptors on T lymphocytes: a solution in sight?

from Melvyn Greaves

A symposium on "Membrane Receptors of Lymphocytes", organised by M. Seligmann, F. Kourilsky and J.-L. Preud'homme, was held in Paris on May 22–24.

THE molecular nature of the cell surface receptor for antigen on T (thymus-derived) lymphocytes has provided one of the central controversies of immunology over the last five or six years. The meeting in Paris produced a major step forward in the resolution of this problem and the closely related question of immune response gene function. Though the meeting included papers on other lymphocyte surface structures including IgD, F₀ receptors, C3 receptors, β₂ microglobulin and Ia antigens, it was the T cell receptor question which once again held the centre of the stage.

Substantial though equivocal evidence had accumulated earlier that the T cell receptor was an immunoglobulin-like molecule—similar if not identical to that on B ('bursa-equivalent' derived) lymphocytes and in serum. The evidence was based partly on the apparent diversity and specificity of T cell responses and also on the capacity of some anti-immunoglobulin sera to block various T-cell activities. But since 1971

three groups of data have considerably influenced research on this question.

First, attempts to chemically identify T cell surface immunoglobulin using lactoperoxidase iodination methods (labelling followed by extraction immunoprecipitation and polyacrylamide gel analysis) have been extensively reported (*Transplantn Rev.*, **14**; 1973). J. J. Marchalonis and colleagues from the Walter and Eliza Hall Institute in Melbourne have maintained that they can reproducibly find considerable quantities of IgM on T cells whereas J Uhr and E. Vitetta (University of Texas, Dallas), R. M. E. Parkhouse and E. Abney (National Institute for Medical Research, London), B. Lisowska-Bernstein and P. Vasalli (University of Geneva) have failed to reproduce this result. Discussion of this discrepancy, centering on technical details, though a regular feature of international conferences, has failed to provide a realistic means of settling the dispute.

Second, the *Ir* ('immune response') gene phenomenon has mushroomed to become a dominant theme of immunology. B. Benacerraf, H. McDevitt and M. Simonson in particular have proclaimed that the T cell receptor was a product of genes linked to the major histocompatibility locus of the species (*H-2* in mice, *HL-A* in man). This speculation was based to a large extent on the view that *Ir* genes were expressed principally at the level of T cells, and on the ability of certain alloantisera directed towards *H-2* or equivalent loci to suppress T cell activity. Third, the discovery that β₂ microglobulin had considerable sequence homology with IgG (see Raff, *Nature*, **254**, 287; 1975) and yet was found associated with HL-A and H-2 on cell surfaces opened up a different philosophical approach to the T cell receptor question. The characteristics of β₂ microglobulin imply that a phylogenetic relationship may exist between immunoglobulin and products of the major histocompatibility locus although there is in man no genetic linkage between genes coding for HL-A, β₂ and immunoglobulin. An evolutionary relationship between HL-A, H-2 and immunoglobulins is further reinforced by recent studies suggesting that the former have an overall tetrameric structure and compact domains that are strikingly similar to those in immunoglobulin molecules (Peterson *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1612; 1975).

This crucial new information supports something of a compromise solution to the T cell receptor mystery since it could be both Ig-like and H-2 (in the mouse)-like! Several authors have suggested for example that it might have an immunoglobulin-like V

region and a constant region coded for by genes linked to the major histocompatibility locus (see for example Gally and Edelman, *A. Rev. Genet*, **6**, 1; 1972).

Two papers on this problem in particular generated a great deal of interest Hans Wigzell (Uppsala University, Sweden) reported on work with Hans Binz which provided very compelling evidence that the same idiotype or variable region gene product can be found on both B and T lymphocytes. The experimental design they used was based on a series of experiments reported several years ago by H. Ramseier (*Transplantn Rev.*, **10**, 57; 1972); these were, in retrospect, outstanding in the extent to which they were ignored or disbelieved by immunologists. In brief, if (P×Q)F₁ animals (rats in this case) are injected with parental P-type lymphocytes then clones of P cells which are specific for Q antigens will proliferate and secrete antibody (if they are B lymphocytes) or become cytotoxic and release 'lymphokines' (if they are T cells). The recognition in this situation might, on genetic grounds, be thought to be entirely unilateral (only P→Q); but P cells do have something which (P×Q)F₁ cells can recognise and presumably lack themselves. This is the idiotype of the anti-Q antibody and the corresponding receptors on the P anti-Q T and B lymphocytes. (P×Q)F₁ rats can indeed be shown to make antibody to this idiotype(s) either in response to the injection of unseparated P cells (or relatively pure T cells from P rats) or to the infusion of P anti-Q serum antibodies. The antibodies so raised react with P anti-Q antibodies, B cell surfaces (about 1% of B cells) and T cell surfaces (about 7% of cells). All the activity against T cells can be absorbed out by either B lymphocytes or P anti-Q antibodies. Preliminary evidence suggests that the idiotypic determinant on B cells was associated with a molecule the same size as 7S IgG (molecular weight 120,000) whereas the T cell product had a molecular weight around 35,000. The latter was non-reducible and therefore possibly a single polypeptide chain. But it cannot at this stage be ruled out that this is an 'incomplete' receptor which is non-covalently bound to other subunits or chains when *in situ* on the cell surface.

Klaus Eichmann (University of Cologne) presented what appears to be a strikingly similar story. He had raised antibodies in guinea pigs to the idiotype(s) of anti-group A streptococci antibodies produced by cloned (*in vivo*) mouse B cells. Although direct binding to T and B lymphocytes was not tested these antisera had very intriguing effects when injected into mice. Anti-idiotype of the IgG2 class suppressed both T ('helper') and B (antibody-forming cell

precursor) responses; whereas IgG1 antibodies stimulated anti-streptococci B clones (at high concentrations) or both B and T anti-streptococci clones (at low concentrations).

These two sets of observations strongly suggest that T cell clones have on their surface a molecular structure—presumably the antigen receptor—which bears idiotypic antigenicity similar if not identical to that of B cell receptors and B cell-derived serum antibodies. Although unequivocal evidence for the biosynthesis of this determinant by T cells is not yet available these results clearly imply that T and B lymphocytes are equipped with a similar 'immunoglobulin' V gene pool and may have at least some identical genes.

Presumably the amino-terminal end of the T cell receptor polypeptide contains both the idiotypic determinant and the antigen combining site. The crucial question now is the nature of the remainder of the molecule. Is it an Ir region gene product with invariant peptide sequences and domains analogous to those coded by immunoglobulin C (constant) genes? If this is the case and V genes are identical in T and B cells we have the problem of how unlinked V and C (I region) gene products become associated, since in B cells the gene pairs are linked and association is believed to occur at the transcriptional level. Alternatively, could the T cell receptor have an immunoglobulin (of a new class?) C region after all? J. Marchalonis and N. Warner suggested that this latter view was strongly supported by their evidence that almost all T-cell derived neoplasms synthesise immunoglobulins. Significantly, with respect to other discriminating lymphocyte cell surface products (for example θ, Ly antigens) these lymphomas maintain a strict T cell phenotype.

The former view is however probably the popular choice and presumably immunochemical analysis of the Wigzell–Binz idiotypically defined T cell product should soon resolve the issue. This interpretation is also supported indirectly by an elegant series of experiments by M Taussig and A. Munro (see this issue of Nature, page 103). Their important and provocative results suggested that activated T cells released an I region coded glycoprotein (molecular weight about 50,000) which facilitates the B cell antibody response. The 'factor' probably has antigen specificity although this critical point has not been clearly established. Mice of different strains which did not respond to (T,G)–A–L may be deficient in T cells producing the factor, in B cells capable of 'receiving' the factor, or both! An observation of paramount importance was the result of crossing

T cell 'deficient' mice with B cell deficient mice; the F₁ offspring were responders presumably by complementation of T and B cell I region-controlled immunocompetence.

A similar Ir gene complementation effect was reported by B. Benacerraf (Harvard Medical School) and was in fact reported with minimal effect by E. Rude and E. Gunther at the Second International Congress of Immunology last year (*Progress in Immunology II*, vol. 2, 223; Associated Scientific, 1974). The main conclusion emerging from the work of Taussig and Munro is that the Ir region may contain structural genes coding for cell surface glycoproteins (with Ia antigenicity) on both T and B cells. These structures are critically involved in antigen recognition and collaborative interactions between T cells, B cells and possibly macrophages as well. If this is correct then the I region contains genes which not only code for antigen binding sites but also for a 'mutual' recognition system (that is, of T cell Ia molecules by B cell surface Ia molecules).

It seems reasonable to suppose that the molecule studied by Taussig and Munro might be the same as the idiotype-bearing structure identified by Wigzell and Binz, although H. McDevitt (Stanford University) reported that anti-Ia sera could not block (T,G)–A–L antigen binding by T (or B) lymphocytes. Taken together however these results certainly created the strong impression that the T cell receptor mystery may be soon solved. In the meantime, some healthy scepticism is probably called for. T cell populations are clearly very heterogeneous and different types of receptors might exist on subsets programmed for distinct functions. The role of macrophage surface structures in the genetic control of T + B responses merits further consideration. The precise antigen specificity and diversity of putative T cell receptors requires clearer definition as do both their immunochemistry and the cellular site of biosynthesis and uptake.

A hundred years ago

IN connection with the calamitous floods around Toulouse, on the 25th June a singular phenomenon was observed at Clermont-sur-Lanquet. The whole of the earth on the slope of a mountain was moved bodily, a shepherd's house being transported uninjured to a distance.

Calcium transport in contraction and secretion

from N. M. Green

The growing interest in the role of Ca²⁺ in a variety of intracellular control mechanisms was reflected in an international symposium on Ca²⁺ transport (Bressanone, May 10–16, 1975) which was devoted to establishing contact between workers in the field of muscular contraction, where the effects of Ca²⁺ are relatively well understood, with those who work on a variety of secretory systems. This report considers only a few of the fifty papers that were presented, emphasising those aspects which may lead to fruitful interactions.

ONE of the main technical problems in the way of a more precise definition of the role of Ca^{2+} in secretory systems is the difficulty of measuring changes in submicromolar, cytoplasmic Ca^{2+} concentrations in the presence of intracellular and extracellular reservoirs where concentrations are increased a thousand-fold. J. Meldolesi (University of Milan) described the analyses of subcellular fractions from pancreas. Interpretation was difficult because of the rapid exchange of Ca^{2+} between compartments after cellular disruption. However, there was an interesting observation of a large non-exchanging reservoir of Ca^{2+} in the zymogen granule fraction. A similar high Ca^{2+} content of secretory granules was observed in pancreatic islet tissue (W. J. Malaisse, University of Brussels) and in parotid gland (Z. Selinger, Hebrew University, Jerusalem). J. L. Borowitz (Purdue University) suggested that uptake of Ca^{2+} by the granules in adrenal medulla might play an auxiliary role in the post-secretory recovery process. A promising new approach to the problem of intracellular Ca^{2+} distribution is that of X-ray microprobe analysis which can detect changes of local concentrations of Ca^{2+} within organelles at a resolution of 50–100 nm, provided that local concentrations, which can be enhanced by microincineration, are high enough (T. A. Hall, Cambridge). A study (with R. Yarom, Hebrew University, Jerusalem) of cardiac muscle revealed unexpectedly high levels in cell nuclei, associated particularly with heterochromatin, suggesting that serious consideration should be given to the nucleus as a reservoir of intracellular Ca^{2+}. M. J. Berridge (University of Cambridge) described another application of the technique to show that

mitochondria of insect (*Calliphora*) salivary gland release their Ca^{2+} following stimulation of secretion by serotonin. Unfortunately, cytoplasmic Ca^{4+} levels are far below the sensitivity of this method, which anyway cannot distinguish free from bound Ca^{2+}. The most suitable technique at present available for measuring free Ca^{2+} is the use of aequorin and it has not yet proved possible to introduce this protein into secretory cells.

Electrophysiological results

Extensive published work by Katz and Miledi has established the existence of time- and potential-dependent channels for Ca^{2+} in synaptic and neuromuscular junctions. The application of similar electrophysiological techniques to secretory systems, partly aimed at testing the wider applicability of these concepts, was described by several groups. E. K. Matthews (University of Cambridge) showed a close correlation between secretion of insulin and spike potentials induced in pancreatic islet cells by D-glucose or by current injection. Since this electrical response depended entirely on the presence of external Ca^{2+} it was possible to calculate from it the magnitude of the Ca^{2+} influx and consequent changes in local internal concentration of the order of 1–2 μM. Glycolytic metabolism was essential to the response implying that the change in permeability was caused by a metabolite rather than by glucose itself. In contrast potential changes in exocrine pancreas induced by acetylcholine or pancreozymin (O. H. Petersen, University of Copenhagen) proved to be Na$^+$ rather than Ca^{2+} dependent implying that the Ca^{2+} known to be required in the activation of secretion was derived from internal stores.

T. J. Rink and P. F. Baker (University of Cambridge) showed that K$^+$ depolarisation of the adrenal medulla gave rise to a time dependent influx of Ca^{2+} which decayed with the half life of 45 s, very much slower than the corresponding effects in nerve and muscle. J. J. Dreifuss and J J. Nordmann (University of Geneva) measured neurohypophysial influx and efflux of ^{45}Ca^{2+} following K$^+$ depolarisation. In this system, as in nerve axons, the Ca^{2+} efflux associated with the recovery phase appears to be driven by Na$^+$ influx rather than being directly coupled to ATP hydrolysis as in muscle. The Ca^{2+} influx was blocked competitively by micromolar concentrations of D.600 (methoxyverapamil). The use of this drug as a Ca^{2+} antagonist follows from the extensive work of A. Fleckenstein (University of Freiburg) who discussed its action on cardiac and on smooth muscle. Its use provided one of the few unifying features of the diverse secretory systems described at

the meeting. Almost all those which required external Ca^{2+} for activation (nerve terminals, neurohypophysis, cardiac muscle, adrenal medulla, endocrine pancreas, insect salivary gland, but not the parotid gland) were inactivated by D.600. It will be of interest to know how far it can be used to characterise molecular species involved in Ca^{2+} conductance. Unfortunately, it has other pharmacological actions as a reserpine analogue. Moreover, N. A. Thorn (University of Copenhagen) reported that in the neurohypophysis it counteracts activation by the Ca^{2+} ionophore A23187, possibly by non-specific complex formation between lipid-soluble amine and carboxylic acid.

The complex interplay between fluxes of Na$^+$ and Ca^{2+} was considered further in several contributions. E. Carafoli (Zurich Institute of Technology) showed that in the absence of permeant anions, Ca^{2+} taken up by isolated heart mitochondria could be released by low (50 mM) Na$^+$. However, Thorn showed that under similar conditions the uptake of Ca^{2+} was also inhibited, throwing some doubt on the interpretation of this result The lack of a defined physiological mechanism for bringing about release of Ca^{2+} from mitochondria makes it difficult to evaluate their role in controlling cytoplasmic concentration, especially since in the long term, as was emphasised by Rink, most of the Ca^{2+} that enters through the plasma membrane must leave by the same route The results of A. B. Borle (University of Pittsburgh) suggesting that cyclic AMP stimulates Ca^{2+} release from isolated mitochondria have not so far proved repeatable. However, Berridge provided evidence for a similar control mechanism to account for his observed release of mitochondrial Ca^{2+} in insect salivary gland Borle emphasised that erroneous conclusions about changes in Ca^{4+} concentrations can easily be drawn from isotopic flux measurements if there is no information about changes in pool size which can be very large.

The actions of cyclic nucleotides in contractile systems are relatively well understood on the biochemical level although the physiological significance is not always clear. S. V. Perry (University of Birmingham) described how the effects of Ca^{2+} in releasing actomyosin from inhibition by the troponin complex are modulated by phosphorylation of the troponin components I and T by either a cyclic AMP dependent protein kinase or by phosphorylase kinase The phosphorylated amino acids have now been located in the sequences of the troponin components, but the way in which phosphorylation and dephosphorylation control sensitivity to Ca^{2+} remains obscure. Cyclic AMP has

a more clearly defined role in controlling the activity of cardiac muscle in response to adrenaline. A. M. Katz (Mount Sinai Hospital) showed that it could enhance the rate of Ca^{2+} uptake by the sarcoplasmic reticulum by activating the phosphorylation of a membrane protein (molecular weight 22,000) by a protein kinase. This phosphorylation was correlated with an enhanced relaxation rate.

It is likely that one direct relation between contraction and secretion will eventually be found at the level of the contractile process itself, since there is a plausible assumption in the field, though little direct evidence, that expulsion of secretory granules is powered by Ca^{2+}-activated actomyosin within the cell. Surprisingly, little was said about this aspect of the relationship, although several interesting papers were given summarising current knowledge in the field of troponin–tropomyosin–actin interactions and the dependence of their association on Ca^{2+} concentration. S. Hitchcock and J. Kendrick-Jones (University of Cambridge) found no functional relation between carp parvalbumins or myosin light chains and the Ca^{2+}-binding troponin component (C) in spite of significant structural homologies, discussed by R. Kretsinger (University of Virginia). Their work on the Ca^{2+}-dependent regulatory properties of myosin light chains in scallop muscle as well as the differences in mode of action of troponins from cardiac and smooth muscle described by S. Ebashi (University of Tokyo), emphasise that control of cellular actomyosin is likely to differ significantly from that of skeletal muscle.

Although initiation of relaxation in skeletal muscle by the sarcoplasmic reticulum is well understood, our knowledge of the mode of control of Ca^{2+} influx in muscle appears little further advanced than it is in secretory systems. The once favoured regenerative release of Ca^{2+} from sarcoplasmic reticulum by local high Ca^{2+} was re-evaluated by M. Endo (University of Tohoku), who showed that unphysiologically high Ca^{2+} concentrations were required and that the process was inhibited by procaine which does not affect the physiological, depolarisation-induced release It would be of interest to know if the Ca^{2+} channels involved resemble those of nerve, heart muscle and secretory tissue in their susceptibility to the action of D.600.

The meeting usefully defined several borderline areas where more work could profitably be done, as well as emphasising the relation of contraction and secretion to more general intracellular control processes involving Ca^{2+} and cyclic nucleotides which were not directly considered.

review article

A hundred years of controversy over sunspots and weather

A. J. Meadows*

After a century of accumulating correlations on the activity of sunspots and atmospheric phenomena around the Earth, we still have no clear idea what exactly the relationships are or what they mean. Much of what is being researched now was already under discussion in the nineteenth century. This article is based on the author's recent Norman Lockyer Lecture at the University of Exeter.

ALTHOUGH the appearance and disappearance of sunspots was one of the first discoveries made with the newly invented telescope in the early seventeenth century, detailed studies with reasonably powerful telescopes had to await the resurgence of interest in solar studies that characterised the latter part of the eighteenth century. One factor in this renewed interest was the possible effect of solar changes on the Earth. William Herschel[1] carried out a detailed study of the solar surface during the period 1795–1800, and, having outlined his results, commented· "Since experience has already convinced us, that our seasons are sometimes very severe, and at other times very mild, it remains only to be considered whether we should ascribe this difference immediately to a more or less copious emission of the solar beams."

He then attempted to find some systematic variation in terrestrial weather that could be linked with changes on the Sun. The only relevant long period data available were some statistics on wheat prices collected by Adam Smith in preparing his book on *The Wealth of Nations*. Herschel assumed these would reflect the average weather conditions in each year, and attributed the fluctuations they showed to solar variation.

This initiative was not followed up for several decades. Herschel's emphasis on the physical properties of celestial objects, although not unique, was hardly characteristic of the first half of the nineteenth century. It was only in the 1860s that the new science of astrophysics became firmly established, and the possibility of a relationship between solar change and terrestrial weather once again came to the fore. By this time, two important observational advances had been made. First, Schwabe in Germany had pointed out that the number of spots visible on the Sun's surface rose and fell in a regular manner with a period of about ten years. Although he announced this result in the early 1840s, it was the early 1850s before it became generally known. Also during the early 1850s, it was found that the frequency of magnetic storms varied with the same period as the sunspots. Thus, by the 1860s, astronomers knew two things that William Herschel did not: that some changes of the solar surface occurred in a cyclical fashion, and that one indisputable relationship existed between solar and terrestrial changes. The latter encouraged the hope that further relationships might be found: the former suggested the way in which they might be sought.

* Department of Astronomy and History of Science, University of Leicester, Leicester LE1 7RH, UK

Lockyer in 1872 asked the readers of *Nature*, "why it is that meteorologists, state endowed or otherwise, have, as a rule, been content to grope their way in the dark, and not only not seek to find, but persistently refuse the clue, which, if followed, would bring them into the light of day[2]" He then explained what this clue was: "Surely in meteorology as in astronomy, the thing to hunt down is a cycle."

The problem from the beginning was that terrestrial weather obviously underwent major fluctuations from day to day. Thus, if cyclical effects extending over several years were to be discovered, it was either necessary to find a clear-cut meteorological phenomenon that showed minimum short-period fluctuations, or to take ordinary meteorological phenomena and look for systematic trends by averaging over large numbers of observations. Several people, Lockyer among them, saw the monsoons in the Indian Ocean as the sort of clear-cut phenomenon that should readily show the effects of solar change Lockyer chanced on this idea : Meldrum, who was in charge of meteorological observations on Mauritius, approached the problem a good deal more systematically. He examined the number, size and duration of cyclones occurring in the Indian Ocean during the period 1847–73, and showed that all these variables were enhanced at solar maximum compared with minimum. He also ingeniously correlated the sunspot cycle with the number of vessels putting into Mauritius for repair after damage caused by heavy seas His extracts[3] from the official port records make livelier reading than most sets of statistics, for example: "December 16–17, 1867 Ship 'Berar', in 24°S and 68°E, experienced a heavy gale, with thunder and lightening; ship hove on her beam ends; cut away top gallant mast, every plate, all clothing, and every book on board washed away. Barometer 29.30 inches."

While Meldrum was putting together figures for the Indian Ocean, Pogson, then Government Astronomer in Madras, was examining weather data for South-east India. His analysis led him to conclude that there was a correlation in that area, too, between variations in the rainfall and the sunspot cycle.

This concentration of effort on the weather of the Indian subcontinent and its environs was not dictated solely by the apparent simplicity of the weather cycle there. The problem of famine was then particularly evident in India— one series of famines in the 1860s being followed by another, even more acute, in the 1870s. As is evident from the meetings of the Indian Famine Commission at the end of the latter decade, the possibility of forecasting future famines

Table 1 Rainfall (Paris) and sunspot cycle for the years 1824–1867

Number of year in mean cycle	Rainfall variation (inch)	Spot variation (number)
1	−2.0	−38 2
2	−0.9	−22.7
3	+0.8	− 5 7
4	+1 9	+33.3
5	+1.9	+41.9
6	+1 8	+30,7
7	+1.1	+13.1
8	+0.2	− 1.5
9	−0.5	−12.1
10	−0.8	−21.7
11	−2.0	−28.0

was under urgent discussion, and the discovery of correlations with the solar cycle seemed to offer the best hope of achieving this.

Studies of weather variation in other parts of the world were being conducted simultaneously, often by the same investigators. Typically, these consisted of an examination either of an extended time sequence of observations made at a single station, or of a shorter time sequence averaged over several stations. Thus Meldrum correlated sunspot numbers with rainfall data measured at the Paris Observatory. As the Observatory had been founded in the seventeenth century, it could provide almost two hundred years of observational material. (The sunspot cycle also had to be extrapolated over this period, of course, and Meldrum, like virtually all his contemporaries, made use of an extensive study of solar records carried out by Wolf at Zurich and published in the 1870s.) Meldrum then studied four spot cycles in more detail, using a shorter time base but averaging over more than 150 observing stations dotted all round the world (see Table 1). In both instances, he found an apparent correlation between the phase of the solar cycle and the weather record.

Rainfall was by no means the only parameter used to characterise terrestrial weather Balfour Stewart used, in addition, atmospheric temperatures and the heights of rivers; whereas W. S. Jevons returned to Herschel's original approach, and linked the number of spots with the business cycle. But the variable that seemed to offer the best chance of providing a physical interpretation of the Sun–Earth interaction was the atmospheric pressure. Blanford[4]—yet another meteorologist working in India—developed the concept of a "barometric seesaw"; by which he meant an oscillation in pressure between two parts of the globe, that varied with the period of the solar cycle

"Between Russia and Western Siberia on the one hand, and the Indo–Malayan region (perhaps including the Chinese region) on the other, there is a reciprocating and cyclical oscillation of atmospheric pressure; such that the pressure is at a maximum in Western Siberia and Russia about the epoch of maximum sunspots, and in the Indo–Malayan area at that of minimum sunspots."

He interpreted this in terms of varying energy supply from the Sun, which led to an alteration in the amount of water evaporating into the atmosphere. This produced, in turn, fluctuations in pressure, temperature and rainfall.

In view of the numerous correlations between the solar cycle and the weather that were discovered in the last quarter of the nineteenth century, it seems at first sight surprising that the century ended with the matter still a focus for controversy. Three reasons can be discerned for the continued doubt.

These correlations represented the result of averaging over widely varying sets of values: their credibility therefore remained dubious in many eyes. As Blanford, who believed in the correlations, remarked, "The amount of the variation is so small in comparison with the irregular

vicissitudes of the weather, that it is for the most part obscured and unrecognisable, except fitfully, or in some few favoured regions."[5] The physical mechanism by which the solar–terrestrial interaction operated still remained unclear in spite of numerous speculations. Moreover, the observations seemed to support contradictory conclusions: the measurements of air temperature suggested greatest solar luminosity at sunspot minimum, whereas the study of rainfall and cyclones suggested greatest luminosity at maximum. It was expected that the discovery of correlations would lead on to the prediction, at least in general terms, of future changes in the weather. Yet even the intensive study of the Indian monsoons failed to lead to an acceptable forecast of famine conditions.

The main sticking point was the uncertainty regarding the exact nature of the supposed solar luminosity variations Not only were the observations contradictory: so were opinions regarding the nature of the variations. The original idea had been that spots blanketed a part of the solar surface, thus reducing the energy emitted, and producing minimum flux at sunspot maximum. By the early twentieth century, it was, on the contrary, even being contended that the luminosity variations might rather be the result of changing numbers of solar prominences, so that maximum luminosity emitted might actually coincide with maximum spot number[6]. The obvious way of resolving this uncertainty was to make a series of direct measurements of the energy received by the Earth during a solar cycle. Throughout the nineteenth century, however, techniques were acknowledged to be insufficiently accurate for this kind of monitoring. There were, in fact, two obstacles in the way of measuring the solar constant. The first was the obvious need to develop a sufficiently sensitive bolometer. But the measurements had to be made at the bottom of the Earth's atmosphere; so, secondly, the effects of fluctuations in atmospheric transmission had to be eliminated. This effectively ruled out the British Isles as a site for the appropriate observations. In fact, interest in possible relationships between solar activity and the weather was clearly on the wane in this country just before World War I, and the renewed attack on the solar luminosity problem took place instead in the USA.

The Smithsonian Astrophysical Observatory in Washington had been involved since its foundation in 1890 in measuring the solar constant. Under Langley, the Observatory's first director, the main concern had been to develop as sensitive and accurate an instrument for this purpose as possible. But C. G. Abbot, the second director, decided not long before World War I that sufficiently good results were being obtained for small changes in the solar constant to be detectable. During the 1920s and 1930s he pushed ahead with the measurements, finding, so he believed, definite evidence for a variation in the solar luminosity from year to year which could be correlated with weather conditions on Earth.

Yet, in spite of this massive effort, *Nature* commented without fear of contradiction at the beginning of World War II that: "Many attempts have been made in the past to correlate solar and terrestrial phenomena . . . There is no direct meteorological effect of any serious importance."[7]

Partly, no doubt, this could be explained by British insularity; for studies of Sun–weather relationships had been at a low ebb in this country since before World War I. But the Smithsonian results were also received with scepticism by many in the USA. The doubts were once more engendered by the difficulty of unravelling a small signal from a large amount of noise: most of Abbot's peers felt that, although his conclusions might ultimately prove to be right, they had not been definitely established. The apparent variations in solar energy might actually be caused by systematic errors, for example in correcting for the influence of the Earth's atmosphere.

Although Abbot continued to stress the significance of the Smithsonian results, the general feeling among both British and American scientists in the years following World War II seems to have hardened towards the view that the total energy emitted by the Sun did not vary appreciably during the solar cycle. This belief, which has strengthened with time[8], obviously rules out the kind of interaction mechanism that was being considered before World War I. It is hardly surprising that interest in the whole subject of solar activity and the weather continued to flag. (Although discussions on the topic continued in the Soviet Union, they were relatively little noticed in the West.) The return of interest only followed, belatedly, after the growth of solar system studies in the 1960s.

The actual correlations studied in the last five years, or so, have not differed very greatly in principle from those we have noted before, although the amount of data that can be collected and reduced has now become a good deal larger Thus one recent attempt to find correlations made use of a study of some ten million different measurements of air temperature[9]. But the crucial point has remained the question of the mechanism involved. However many numbers are invoked, the old doubts are unlikely to be resolved so long as all that can be offered is statistical regularities. If the Sun's luminosity can no longer be regarded as a variable, attention must naturally turn to those features of the Sun that might affect the Earth and that are certainly known to vary during the solar cycle—magnetic fields, particle emission and high energy radiation.

It has long been realised that changes in the upper atmosphere of the Earth can be related to the solar cycle. Balfour Stewart—one of the first to realise that the Earth's upper atmosphere is electrically conducting—attempted to correlate variations in terrestrial temperature and magnetic declination. The interactions here are between the Sun and the ionised upper atmosphere. In the 1960s, it became apparent that the neutral upper atmosphere was also strongly influenced by solar activity, and the belief grew that there might be further interaction with the lower atmosphere. The difference in the masses of the upper and lower atmosphere, however, suggested that such a link could not be direct, rather it would have to occur by some kind of trigger action, so that a small effect in the upper

atmosphere could produce a major effect in the lower atmosphere by way of an instability. An intriguing recent claim—that solar magnetic sector structure can influence terrestrial atmospheric vorticity[10]—may indicate the sort of direction in which this instability should be sought. Unfortunately, there is no scarcity of competitors.

As I have remarked, one thing a satisfactory Sun–weather relationship should be able to do is to forecast future changes in the weather. This obviously requires an ability to predict future solar activity; so it must surely rank as more than a coincidence that interest in such powers of prediction accompanied the upsurge of activity in correlating solar and terrestrial changes both in the nineteenth century and today. Even more interestingly, attempts have been made on both occasions to relate solar activity—measured by sunspot numbers—with particular alignments of the planets[11,12]. Although the exact mechanisms have differed, the significance of such correlations is that, if true, they should permit the forecasting of solar activity for any time in the future, as planetary orbits are very well determined. It is a commentary on the overall problem of establishing anything firmly in this field that, both in the nineteenth century and now, there have been strong counterclaims that the apparent coincidences between planetary positions and sunspot numbers are simply figments of the analysis[13].

Would it then be fair to conclude with Solomon that there is no new thing under the Sun? Not entirely—for, although in one sense additional correlations may add nothing new, they may lead to an acceptable mechanism for the necessary interaction between the Sun and the lower atmosphere of the Earth If this could only be defined, the whole controversial field might be rapidly translated into the realms of high respectability.

Packaging of prophage and host DNA by coliphage λ

Nat Sternberg & Robert Weisberg

Laboratory of Molecular Genetics, National Institute of Child Health and Human Development, Bethesda, Maryland 20014

Bacteriophage λ can package headfuls of prophage and host DNA. The resulting particles are not infective without removal in vitro of unpackaged DNA that protrudes from the head and prevents the attachment of tails. After tail attachment the particles can transduce a large number of host genes.

THE DNA of the phage λ virion (mature DNA) is a double-stranded molecule about 47,000 base pairs long with specific single-stranded sequences, 12 bases long, at each 5′-phosphate end[1,2] (Fig. 1a). The left end sequence is complementary to the right end sequence; this enables circularisation of a molecule by base-pairing of the ends[3]. Mature DNA is formed by the cutting to size of a longer precursor, a linear polymer of mature molecules joined together head-to-tail
Fig. 1 *a*, Each strand of the DNA of the λ virion is represented by a straight line. The symbols above the double line give the order on the phage genetic map of λ genes mentioned in the text[55]. The distances between genes are arbitrary. The left and right ends of the DNA (within the circles) are shown in expanded scale to the left and right with the vertical bars representing bonds between base pairs, *b*, The inserted prophage and adjoining bacterial DNA are represented according to the same convention except that the bacterial DNA strands are shown by broken lines. Insertion occurs by reciprocal recombination between the site denoted *att* in *a* and another *att* in the bacterial DNA (ref. 26). During insertion the left and right ends of mature DNA are joined by base pairing and ligation[6,26,31]. Consequently the prophage map is a cyclic permutation of the phage map, with the joined ends (within the circle under *cos*) approximately in the centre. *gal* and *bio* are bacterial operons closely linked to the prophage[33]. *c*, Chromosomes of λ*docL* and λ*docR* are represented according to the same convention. The cutting and packaging of these DNAs are described in the text

by covalent bonds[4,5]. This is thought to occur as follows[6-9]. The products of λ genes *A* and *D*, in conjunction with a phage head precursor, make two staggered, single-stranded endonucleolytic cuts 12 base pairs apart at the regions of the polymer corresponding to the mature ends. The sequence-specific cutting activity is called Ter, for terminase, and its site of action is called *cos* (for cohesive end site). The DNA between an adjacent pair of cuts is condensed by an unknown mechanism to approximately 15 times its previous concentration[10] and packaged into a phage head. Cutting and packaging have a common requirement for several phage and at least one host gene[11,12]. Thus, the two reactions are coupled.

DNA cutting by λ differs from that by phage T4 (ref. 13) and phage P22 (ref. 14). Although both of these phages, like λ, cut and package DNA from continuous linear polymers, the length of the mature DNA is determined not by the distance between two specific cutting sites but by the capacity of the head; that is, headfuls of DNA, each slightly larger than the genome, are cut from the polymer. T4 DNA cutting seems to involve no unique recognition site on the DNA. In contrast, mature P22 DNA is formed by sequential cutting and packaging of headfuls from a unique starting site on a polymer[15]. The latter phage, therefore, combines some of the elements of both site-specific and headful cutting.

We report here the production of variant λ particles whose DNA, like that of T4 and P22, is packaged by the headful. These particles are the major product of phage growth when normal packaging is suppressed by the elimination of polymeric λ DNA. In such lysates we also find transducing activity for a large number of bacterial genes. The particles responsible for such activity seem to

be formed by the packaging of headfuls of bacterial DNA in λ capsids.

Packaging of prophage DNA

To examine packaging in the absence of polymeric λ DNA, we characterised the phage particles released after induction of an excision-defective monolysogen. In such a lysogen, phage DNA replication initiates in the prophage at *ori* (Fig. 1*b*) and then proceeds in both directions in the bacterial chromosome[16,17]. The structure formed after several rounds of DNA synthesis have initiated is not known with certainty; it probably resembles a puff of localised replication around the prophage. If so, the prophage replicas would be colinear with an unreplicated prophage (Fig. 1*b*).

How is such DNA packaged? We propose the following model. Ter cuts the prophage at *cos* to form the normal left and right ends of mature λ DNA. DNA to the right of *cos* is preferentially condensed and packaged in phage heads. The amount of DNA per head equals the capacity of the head (a headful). Unpackaged DNA, continuous with the packaged DNA, protrudes from the head, blocking the attachment of tails and preventing the function of λ protein(s) that act at the head–tail junction

Some evidence for this model already exists Gottesman and Yarmolinsky[18] and Little and Gottesman[19] showed that Ter cuts *cos* after induction of an excision-defective lysogen. They also characterised the DNAs of two types of defective phage particles produced· λ*docL* and λ*docR*. λ*docL* DNA carries the left end and λ*docR* DNA the right end of mature λ DNA; both DNAs are colinear with the prophage and in addition carry adjacent bacterial genes (Fig. 1*c*). We have further characterised λ*docL* particles and measured

Table 1 Plaque formers and *bio* transducers produced after induction of an excision-defective monolysogen (strain NS490)

Activity	Units per induced cell		+DNase
	+DNase	−DNase	−DNase
Bio transduction	2×10^{-2}	3.3×10^{-4}	60
Plaque formation	3.8×10^{-5}	3.6×10^{-5}	1.0

The relevant genotype of NS490 is: *supOrecA(λb2red3cIts857 Sam7)*. The excision defect of NS490 is a consequence of inactivation of the right prophage attachment site by the *b2* mutation[18]. A lysate was prepared by heat induction of NS490 as follows. Cells were diluted from a fresh overnight culture into tryptone broth (1 % Difco tryptone, 0 5 % NaCl in distilled water) and grown in a shaking water bath with vigorous aeration at 32 °C to $A_{630} = 0.4$ (this corresponds to 2×10^8 viable cells ml^{-1}). At this point the temperature of the culture was raised rapidly to 42 °C for 15 min and then lowered to 38 °C. After 135 min of incubation at 38 °C the cells were collected by centrifugation, resuspended in 0 02 volume TMG (0.01 M Tris-HCl, *pH* 7 4, 0.01 M MgSO₄, and 0.01 % gelatin) with or without the addition of pancreatic DNase (10 μg ml⁻¹)(Worthington, RNase-free), and incubated with gentle shaking for 30 min at 32 °C together with CHCl₃ (about 0.05 ml ml⁻¹) to promote lysis. The biological activity of such lysates was stable at 4 °C. *Bio* transducers were assayed by infecting a starved overnight culture carrying the *bio*A24 mutation[49] with appropriate dilutions of the above lysate together with five *λcIts857* phage per cell. After 15 min incubation at 32 °C for phage adsorption, a constant number of cells (approximately 10⁸) was added to 2.5 ml molten 0.7% agar in distilled water, and poured into Petri plates containing about 40 ml M9 agar[50] supplemented with 0.5 % glucose, 0.5 % Difco vitamin-free casamino acids, and thiamine (0.1 μg ml⁻¹). Colonies of *bio*⁺ transductants were counted after 24 h incubation at 32 °C. Plaque formers were assayed on strain YMC (*supF*⁺). Plaque formation and the growth of bacterial cultures for transduction were as described[50].

the number produced per cell relative to λ*docR*. The results of these studies are presented next.

Packaging of DNA to the right of *cos*

Our model predicts that an excision-defective lysogen will produce tailless phage heads carrying λ*docL* DNA. In fact, λ*docL* particles, as originally characterised, were uninfective, seemingly because they lacked tails[19] If tail attachment to λ*docL* is prevented by uncut DNA protruding from

Table 2 Requirements for extra cellular maturation of λ*docL* particles

Limiting gene products	Relative infectivity of:	
	λ*docL*	λ*docR*
None	1.0	1.0
J	0.02	1.0
W	0.95	1.0
FII	0.02	1 0

A culture of NS490 was induced and collected as described in Table 1 and then mixed with an induced culture of a second lysogen (see below) in TMG to give about 10⁸ and 10¹⁰ cells per ml, respectively, of the two strains After 10 min incubation at 32 °C in the presence of CHCl₃ (0.05 ml ml⁻¹), DNase (10 μg ml⁻¹) was added and incubation continued for 30 min. The mixtures were then assayed for transducing particles. The numbers in column 2 (λ*docL*) are relative numbers of *bio* transductants (see Table 1). The value 1.0 corresponds to 0 01 *bio* transductants per input NS490 cell When DNase was omitted from the mixture, this value fell to 0.0003 *bio* transductant per NS490. The numbers in column 3 (λ*docR*) are relative numbers of *gal* transductants. A value of 1.0 corresponds to 0.002 *gal* transductants per input NS490. *gal* transduction was measured as described in ref. 50 with strain SA624 (*galT*amA28)[51] as recipient. The second lysogen was always a derivative of strain 594 (*supO strR galK2 galT1*) It was induced and collected as described in the legend to Table 1 for strain NS490. The prophage varied: in line (1), (None), it was λ*Eam4 cIts857 Sam7*, in line (2), (J), λ*Eam4 Jam27 cIts857 Sam7*; in line (3), (W), λ*Wam403 Eam1100 cIts857 Sam7*; and in line (4), (FII), λ*Eam11 01 FIIam423 cIts857 Sam7*. The purpose of the mutations in gene *E*, which encodes the major λ head protein, was to prevent the trapping of other phage proteins in or on head structures made of *E* protein, and to prevent the formation of *bio*-transducing particles by strain 594 lysogens.

the phage head, removal of the excess DNA should lift the block We indeed observed a large increase in infectivity, measured by *bio* transduction, when we treated a λ*docL* lysate with DNase (Table 1, line 1). In contrast, DNase treatment did not increase the infectivity of plaque-forming λ in the same lysate (Table 1, line 2). The latter particles presumably have normal left and right DNA ends as both are required for autonomous phage growth[20,21]. Therefore we do not expect that any DNA will protrude from the head and block tail addition.

If *bio*-transducing particles arise from λ*docL* heads, they will carry the left end of wild-type λ DNA and phage genes from the left arm of the λ chromosome. These predictions are confirmed by the following observations (the data will be presented elsewhere). The *bio*-transducing activity can be concentrated and purified by standard techniques (see Table 4) DNA extracted from purified particles carried the left but not the right end of wild-type λ DNA (ref. 22 and K. Murray, personal communication). The presence of the left end is consistent with the observation that this DNA possessed high transforming activity for *bio* in the transformation assay described by Kaiser and Hogness[23]; such activity requires that the DNA carry at least one λ end[24] This DNA has been restricted by treatment with endonuclease R.*Eco*RI, and the resulting fragments resolved by electrophoresis in agarose gels One of these fragments was indistinguishable in size from that of a 0.44 fractional length fragment cleaved from the left arm of λ DNA by the same enzyme (ref. 25 and D. Tiemeier, personal communication). If the DNA of the *bio*-transducing particles carries only one of the λ ends, it will be unable to circularise and therefore to form a prophage[26]. In fact,
Fig. 2 The kinetics of the *in vitro* completion of λ*docL* virions. λ *doc* particles were produced by induction of *supO recA* (λ*Jam6 b2 red3 cIts857 Sam7*) as described in Table 1, without the addition of DNase. λ tails were produced in the same way by induction of strain 594 (λ*Wam403 Eam1100 cIts857 Sam7*), (see Table 2). Samples (0.2 ml) of the first lysate containing one drop CHCl₃ were preincubated for 40 min at 32 °C in the presence (+DNase) or absence (−DNase) of DNase (0.2 μg ml⁻¹). After this preincubation period (0 min on the figure) the following additions were made to the samples and aliquots were removed at the designated times to assay λ*docL* (*bio* transduction) or λ*docR* (*gal* transduction): ○, (+DNase)+0.2 ml tails, λ*docL* assayed; ■, (−DNase)+0.2 ml tails, λ*docL* assayed; □, (+DNase)+0.2 ml TMG, λ*docL* assayed; ▲, (−DNase)+0.2 ml tails+DNase (0.2 μg ml⁻¹), λ*docL* assayed; ●, (−DNase) +0.2 ml tails+DNase (0 2 μg ml⁻¹), λ*docR* assayed; △, (−DNase)+0.2 ml tails+DNase (10μg ml⁻¹), λ*docL* assayed. The final yield of λ*docL* obtained in the presence of DNase and tails was 0.007-0.008 *bio* transductants per input *recA* cell. This is 70-80 % of that obtained when the λ*doc* lysate, tails and DNase (10 μg ml⁻¹) were mixed immediately after lysis Preincubation of the lysate for 40 min in the presence of tails followed by the addition of DNase (0.2 μg ml⁻¹) gave results identical to ▲. The final yield (0.0007 *gal* transductants per input *recA* cell) and kinetics of formation of λ*docR* were the same in the presence as in the absence of DNase.

Fig. 3 Models for the packaging of prophage and polymeric DNA. *a*, First step in the packaging of prophage DNA is the cutting of *cos* and the encapsulation of DNA to its right by precursor head I together with the products of genes *A*, *D*, *F*I and *W*. The work of several groups shows that the formation of precursor head I (prehead or petit λ) requires the function of phage genes *B*, *C*, *nu*3 and *E* (refs 8, 56 and 57), while the products of genes *A*, *D*, *F*I and *W* act subsequently[7,8,29,40]. All of these genes are required for λ*doc*L production (data not shown). Packaged duplex DNA is shown as a coil; unpackaged duplex DNA as a straight or wavy line. In the lysate, the excess DNA protruding from precursor head II is trimmed by DNase action and the λ*doc*L particle is completed by the addition of *F*II protein and tails. *b*, Packaging of polymeric DNA differs from that of the prophage in that adjacent copies of *cos* are both cut, and the intervening DNA is packaged. Therefore, no excess DNA protrudes from the head, and *F*II protein and tails add intracellularly. We show DNA associated with the tail of λ but not with that of λ*doc*L (J. Thomas, N.S. and R.W., unpublished).

less than 1% of the *bio* transductants were lysogens. We have observed cotransduction of the *bio*A gene with λ left phage arm genes *B*, *D*, and *J* by using *bio*A recipients that carried suitably marked prophages. In the light of these observations, we refer here to the *bio*-transducing particles as λ*doc*L particles.

The hypothesis that functional tails add to λ*doc*L heads only after extracellular DNase treatment is confirmed by the following experiment. An induced excision-defective lysogen was diluted 100-fold with a second induced lysogen that carried a λ*J*⁻ prophage, and the mixture was lysed by adding chloroform followed by DNase. Only the excision-defective prophage can synthesise tails[27,28]; thus, we predict that the formation of infective λ*doc*L should be limited by the low concentration of tails in this mixture. In fact, the number of *bio* transducers was 30-fold less than that found when the excision-defective lysogen was diluted with a tail-proficient lysogen (Table 2, lines 1 and 2). In contrast, the infectivity of phage particles whose DNA carried a wild-type λ right end (λ*doc*R; Fig. 1c,) was unaffected by dilution with a tail-defective lysogen (Table 2). These observations show that the attachment of functional tails to λ*doc*L heads occurs extracellularly, whereas attachment to

λ*doc*R heads occurs intracellularly. Is this also true of λ proteins that act at the head–tail junction? To answer this question we diluted the λ*doc*L-producing lysogen before lysis with a *W*-defective or an *F*II-defective lysogen. The protein products of the *W* and *F*II genes are known to act sequentially on DNA-filled heads to permit the attachment of tails[29]. After lysis of the mixtures, we found normal levels of *bio*-transducing activity in the *W*-deficient but not in the *F*II-deficient mixture (Table 2, lines 3 and 4). We conclude that *W* but not *F*II product can act on λ*doc*L heads intracellularly.

The above conclusions are consistent with the effect of varying the order of addition of tails and DNase on the subsequent rate of formation of infective λ*doc*L. Figure 2 shows that if tails were added to a tailless λ*doc* lysate before or at the same time as DNase, there was a delay in the formation of infective λ*doc*L relative to λ*doc*R. The delay was eliminated when DNase was added to the lysate before tails. We conclude that DNA must be digested before functional tails can add to λ*doc*L heads. We suspect this is also true for the action of *F*II product.

Our model of the formation of λ*doc*L is compared with the formation of λ in Fig. 3.

Capacity of head and asymmetry of packaging

The amount of DNA per λdocL particle that remains after DNase treatment should correspond to the capacity of the λ head (Fig. 3). This prediction can be verified by equilibrium density gradient centrifugation of a DNase-treated λdocL lysate, as the density of a λ particle (and presumably of a λdocL particle) is a known function of its DNA content[1]. The results of such an experiment (Fig. 4) show that the density profile of bio-transducing activity had a peak corresponding to a DNA content 104% that of wild-type λ and a width suggesting some heterogeneity in the amount of DNA per particle. This is about the maximum amount of DNA that can be packaged in a λ head without a reduction of phage growth: a phage mutant with a DNA content of 109% had a burst size only 10% that of wild-type λ, and this reduction is directly attributable to the increased DNA size[30]. A mutant with a DNA content of 106.5% (λimm434att[2]) had a larger but still reduced burst (N.S. and R.W., unpublished).

In addition to λdocL, an excision-defective lysogen produces another particle, λdocR, whose DNA consists of the right arm of the λ chromosome and bacterial DNA to the left of attλ. It is formed by the packaging of prophage and bacterial DNA to the left of cos[19] (Fig. 1c). λdocR can be physically separated from λdocL by equilibrium density gradient centrifugation (see ref 19 for the density distribution of λdocR). We found that the number of λdocL particles in a lysate exceeded that of λdocR by a factor of 200–600 (Table 3, column 2). The great excess of λdocL relative to λdocR confirms our hypothesis that DNA to the right of cos is packaged preferentially. Data to be presented elsewhere suggest that this asymmetry is a consequence of asymmetry in cos (N.S. and R.W., unpublished).

How is λdocR DNA cut from the bacterial chromosome? At present, we can only offer a tentative answer to this question. The right end of λdocR DNA must be formed by Ter acting specifically at cos; the left end may be formed through nonspecific cutting by Ter or by some other intra-cellular nuclease. Little and Gottesman[19] have shown that the left end is not at a specific site. The DNase independence of λdocR infectivity (data not shown) suggests that the left end is formed intracellularly.

While measuring the number of particles in λdoc lysates, we found that the ratio of infective to total particles (the specific infectivity) of λdocR was 100–200 times greater than that of λdocL (Table 3, column 4). This is at least partly explained by the defective DNA injection of λdocL particles (J. Thomas, N.S. and R.W., unpublished) We shall consider this point further below.

Generalised transducing particles

Lysates of an induced excision-defective lysogen also contained particles that transduced many different bacterial genes (Table 4). A detailed analysis of these particles will be presented elsewhere (N.S. and R.W., unpublished); we list here some of their salient properties. Transduction was abolished if the lysate was treated with anti-λ serum or if the bacterial recipient was unable to adsorb λ. Therefore, the activity is associated with λ virions Generalised transducers were found in lysates of recA bacteria infected with λ int⁻red⁻. Therefore, neither prophage insertion[41] nor any of the major recombination pathways of phage or host[32] is required. In fact, the production of generalised transducing particles was reduced by the action of the Red recombination pathway. This observation is not understood. All the transductants examined were haploid and carried no phage markers. This suggests that transduction occurs exclusively by substitution of infecting DNA for homologous recipient DNA. Transduction by substitution is expected if the transducing DNA is unable to circularise[26]. The transducing activity for markers close to attλ was

lower in lysates made by infection than in those made by induction. We attribute this to preferential replication of bacterial genes near the prophage. The transducing activity of a lysate made by infection varied over a 100-fold range for different markers. This suggests that certain regions of the bacterial chromosome are preferentially packaged by λ. Certain pairs of closely linked bacterial markers—such as argH-rif and gal-bio (ref. 33)—were cotransduced by λ. The appearance of generalised transducing activity, like λdocL infectivity, required DNase treatment of the lysate (Table 4) in the presence of FII protein and tails (data not shown). The density distribution of transducing activity for five of six markers examined coincided precisely with that of λdocL (see Fig. 4; his was the exception).

How are generalised transducing particles formed? The following hypothesis, although difficult to test, is appealing because of its simplicity. We assume the existence of sites in the bacterial chromosome whose nucleotide sequence resembles that of cos. These sites are cut with low efficiency
Fig. 4 A CsCl equilibrium density gradient of λdocL. A DNase-treated lysate of strain NS490, prepared as described in Table 1, was partially purified by low speed centrifugation (6,000g for 10 min at 4 °C) followed by centrifugation of the supernatant on a CsCl step gradient for 60 min at 4 °C in a Beckman SW56 rotor. (Four steps of densities 1.7, 1.55, 1.45 and 1.30 g ml⁻³ were used[58].) Fractions were collected from the bottom of the tube and those containing most of λdocR and λdocL infectivity were pooled and dialysed against 0.1 M Tris-HCl, pH 7.4, 0.01 M MgSO₄; 5 μl of this was mixed with 2.484 g solid CsCl and 3.03 ml TMG containing λatt[2] int am29 imm434 cIts1 (ref. 59) and λb2 immλ cI (ref. 18). The DNA content of the former phage is 106.5% (ref. 1 and M. Fiandt, et al. unpublished) and the latter 88% (ref. 1) that of λ. These phage were centrifuged for 22 h at 35,000 r.p.m. in a Beckman SW50 rotor at 4 °C. Sixty-two fractions were collected from a hole punctured in the bottom of the tube and assayed for λdocL (●) (bio transducers; Table 1); trp transducers (△), (using strain C224 trp (λ)[60] as host; Table 4); λatt[2] (○); and λb2 (▲), (turbid and clear plaque formers, respectively, on the non-lysogenic strain C600, plates incubated at 32 °C). The λdocR activity (Table 3) was found in a broad peak within fractions 30–37 (data not shown). Densities were related to DNA contents by the equation of Bellett et al.[61]. In a separate experiment, A₂₆₀ of the fractions was measured as well. The absorbance profile coincided with that of λdocL, the predominant λdoc species (Table 3).

Table 3 Yield per cell of λ*doc*L and λ*doc*R

Phage	Units per induced cell (a) Total particles	(b) Infective particles	Specific infectivity (b / a)
λ*doc*L	4	0.02	0.005
λ*doc*R	0.01–0.02	0.01	0.5–1

A DNase-treated lysate of NS490 derived from 300 l induced cells was prepared as described in Table 1 except that the initial concentration factor was 1,000-fold rather than 50-fold Bacterial debris was removed by low-speed centrifugation, and the phage were sedimented by overnight centrifugation at 6,000g at 4 °C. The pellet was resuspended in 30 ml TMG, and the phage purified by centrifugation first through a CsCl step gradient and then in a CsCl equilibrium gradient. The latter step separates λ*doc*L from λ*doc*R (see Fig. 4). λ*doc*R was assayed by plaque formation on strain N585 (ref. 19), [*sup*0 (λ*Nam*7 *imm*434; 21*hy*5)]. This assay, which depends on recombination between the *imm*λ marker of λ*doc*R and the right arm of the prophage, is about two to fourfold more efficient than *gal* transduction (data not shown). λ*doc*L was assayed by *bio* transduction (see Table 1). To measure total particles, the CsCl equilibrium gradient fractions containing most of the λ*doc*L and λ*doc*R infectivity were pooled separately and dialysed against TMG.A_{260} of each pool was measured and the values obtained converted to numbers of physical particles by assuming that an $A = 1.0$ corresponds to 3×10^{11} plaque-forming units per ml wild-type λ (ref. 52), and that the specific infectivity of wild-type λ is 1.0 The number thus obtained for λ*doc*L was confirmed by comparing the serum blocking power[53,54] of the pooled λ*doc*L with that of λ*cIts857 Sam7* purified in the same way. (The titration of neutralising antiserum with λ virions presumably measures the concentration of tail fibres.) Identical results were obtained with a second 300 l preparation and, for λ*doc*L, with 20 ml lysate labelled with ^{3}H-thymine

by Ter, and adjacent DNA to the right is packaged according to the model we have proposed for λ*doc*L. At present we have insufficient evidence to distinguish this model from one that assumes nonspecific cutting either by Ter or by another nuclease. In addition, it remains to be shown that the transducing particles contain exclusively bacterial DNA. Nevertheless, the coincidence between the density distribution of most of the transducing activity and that of λ*doc*L strongly suggests that λ packages bacterial DNA by the headful in these conditions.

Discussion

How are the packaging of prophage and polymeric DNA related? Our models of the two processes (Fig 3) differ in one important respect: precursor head II, the DNA of which is continuous with unpackaged DNA, is unique to prophage packaging. We know little about the properties of this intermediate and are attempting to confirm its existence by electron microscopic examination of purified preparations. Because of the higher concentration and consequent lower entropy of packaged DNA, we might expect precursor head II to be unstable. On the contrary, it seems to be stable for at least 40 min in a concentrated lysate (Fig. 2). (This conclusion rests on the assumption that a constant fraction of the precursor head II present in concentrated lysate is converted to *bio*-transducing particles by treatment with DNase.) In contrast, similar structures formed during DNA packaging by phages T4 and T7 (prohead III (ref. 34) and the 40S structure[35], respectively) seem to be unstable. This difference may reflect a difference in experimental conditions or a difference in the precursors.

Our results indicate that the prophage DNA to the right of *cos* is packaged more efficiently than DNA to the left. The results of Emmons[36] demonstrated an asymmetry in the packaging of polymeric DNA. He explained this by proposing that packaging initiates at *cos* and proceeds rightwards. This proposal is completely consistent with our findings.

We find that the yield of λ*doc*L particles from an induced excision-defective single lysogen is four per cell (Table 3). This suggests that *cos* is cut at least once in every cell.

Freifelder *et al.*[37] have proposed that two copies of *cos* on a single molecule are required for optimum Ter cutting. Our measurements of the total yield of λ*doc*L do not support this proposal: the yield is no greater in a tandem polylysogen than in a single lysogen even though the production of plaque-forming particles is much higher in the former strain (N.S. and R.W., unpublished). We are measuring the kinetics of λ*doc*L production in the two strains.

The failure of tails to add to precursor head II is not surprising in view of the intimate and specific association between the tail of the wild-type virion and the right end of mature DNA (refs 38 and 39). Incubation of precursor head II with DNase in the presence of *F*II protein and tails markedly increases the infectivity of λ*doc*L (Table 1). Nevertheless, fewer than 1% of the total particles are infective (Table 3). The uninfective particles lack neither tails nor *F*II protein. The presence of tails and therefore of *F*II protein[29,40] is shown by: the concordance of the serum-blocking power with the A_{260} of purified λ*doc*L (see legend to Table 3); the concordance of the CsCl equilibrium density profile of the absorbance with that of the *bio*-transducing activity (see legend to Fig. 4); and electron microscopic observations of the particles adsorbed to bacteria (J. Thomas, N.S. and R.W., unpublished). Therefore, an explanation of the low specific infectivity of λ*doc*L must be sought elsewhere. We find that it results, at least in part, from inefficient DNA injection by tailed particles, and we postpone further discussion to a later paper.

Many bacteriophage species mediate generalised transduction. For some we know that the transducing particles contain little or no phage DNA (ref. 41, 42); apparently these phages can cut and package the bacterial DNA. We suspect that λ generalised transducing particles also contain exclusively bacterial DNA, although this has not been proved. If this DNA is packaged according to the model proposed earlier, only one Ter cut in the bacterial chromosome is needed for each particle. The absence of generalised transduction when DNase is omitted can then be explained by the improbability of finding in the bacterial chromosome two Ter-specific cutting sites that are separated by the length range compatible with phage viability (about 36,000–51,000 base pairs[30,43]).

How do other phages that normally contain DNA with specific ends package bacterial DNA in the absence of DNase? For phage P22 the answer may lie in the model of DNA packaging proposed by Tye *et al.*[15], elaborated by Chelala and Margolin[44]: only the first cut in the bacterial chromosome need be specific; other, nonspecific cuts can

Table 4 Production of generalised transducing particles

Marker transduced	Units per induced cell +DNase	−DNase
*glt*A, *nad*A, *aro*A	10^{-3}	$< 10^{-5}$
*pur*E, *pyr*D	10^{-4}	$< 10^{-6}$
*trp*E, *pro*A	2×10^{-5}	$< 2 \times 10^{-7}$
thr, *leu*, *arg*H, *pyr*C	$2{-}4 \times 10^{-6}$	$< 10^{-8}$
his	5×10^{-7}	$< 10^{-8}$

DNase-treated and untreated lysates of strain NS490, prepared as described in Table 1, were assayed for transducing activity on the following hosts: AB1157, obtained from the NIH collection, for *arg*H, *pro*A, *his*, *leu* and *thr*, X9170 and MP005, obtained from Dr W. Epstein, for *glt*A and *nad*A, respectively; AB478 and MSO, obtained from Dr S. Adhya, for *aro*A and *pyr*D, respectively; X5214, obtained from Dr E. Signer, for *pyr*C; X821, obtained from Dr R. Curtiss III, for *pur*E; and Y *mel trp* E5947, obtained from Dr C. Yanofsky, for *trp*E. All strains not already lysogenic for λ were lysogenised to reduce killing by plaque-forming phage present in the lysate. Transduction was performed as described for *bio* (see Table 1) except that no coinfecting λ was added, and vitamin-free casamino acids were omitted from the plating agar for transduction of *glt*A, *nad*A, *pur*E, *pyr*D, *pro*A, *thr*, *leu*, *arg*H, *pyr*C and *his*.

be made by a nuclease that is associated with the phage head In the case of phage Mu-1 (ref. 45) one end of the phage DNA is known to be variable, both in nucleotide sequence and in length[46]. It is therefore possible that a sequence-specific nuclease cuts one end of both phage and transducing particle DNA, while the other end is cut non-specifically. Generalised transduction by phage T1 (ref. 47) is more difficult to explain Normal T1 DNA is linear with a duplex terminal repetition[48] The extent of the repetition varies slightly in extent at both ends of the DNA (ref. 48). This imprecision in the ends suggests that the T1 DNA cutting mechanism may be more tolerant than that of λ to sequence variability. Alternatively, the production of T1 generalised transducing particles may require a nuclease not normally used to cut the phage DNA.

We thank Drs D. Botstein, M. E. Gottesman and J. Weil for suggestions; and Drs L. Enquist, H. Nash and M. Shulman for criticising the manuscript.

Two genes in the major histocompatibility complex control immune response

A. J. Munro & M. J. Taussig

Immunology Division, Department of Pathology, University of Cambridge, Tennis Court Road, Cambridge CB2 1QP, UK

Antibody production in mice is controlled by two functionally distinct gene types in the I region of the major histocompatibility complex. One controls T cell recognition of antigen and T cell mediators of cell cooperation, and the other controls the B cell response to T cell mediators.

THE immune response to various antigens is under the controlling influence of genes in the major histocompatibility complex (MHC), termed immune response or *Ir* genes[1-3]. These genes are probably present in all vertebrates including man[4,5], where they may influence the outcome of various diseases[5,6]. The responses controlled by these genes are dependent on thymus-derived lymphocytes or T cells, and include cell-mediated immune responses (for example delayed hypersensitivity) and thymus (T)-dependent antibody responses. A major feature of the MHC-linked *Ir* genes is that they show apparent antigen specificity, though they are clearly separate from the genes coding for serum antibody[1-3]. We have been concerned mainly with the role of *Ir* genes in T-dependent antibody responses, especially in the cooperative interaction which is required between T cells and bone-marrow derived lymphocytes (B cells) for the latter to be triggered to antibody production.

In the past, attention has focused on whether the *Ir* genes code for the antigen-recognition system of T cells—that is the T cell antigen receptor[1-3], a structure which is known to exist but which has proved very hard to characterise. A problem with this interpretation of *Ir* gene function has been that in certain experiments—including our own—the locus of the action of *Ir* genes seems to be in B cells[7-10]. These contradictions can be reconciled if there are two kinds of *Ir* gene controlling the response to each antigen, one gene expressed in T cells and the other in B cells, with different functions in each cell type. We have developed assays for the products of the *Ir* genes and found strong evidence to support a two-gene model.

T cell factor

Our experiments have depended on the production by T cells of an antigen-specific molecule termed a T cell 'factor' which is capable of replacing T cells in thymus-dependent antibody responses[11]. Figure 1 summarises the production and assay of this factor. We have shown that the factor carries a binding site for antigen by absorption with antigen-coated columns. Furthermore, the factor is not an immunoglobulin—it has a molecular weight of about 50,000, and does not react with anti-immunoglobulin reagents. On the other hand, the factor

Preparation of antigen-specific factor

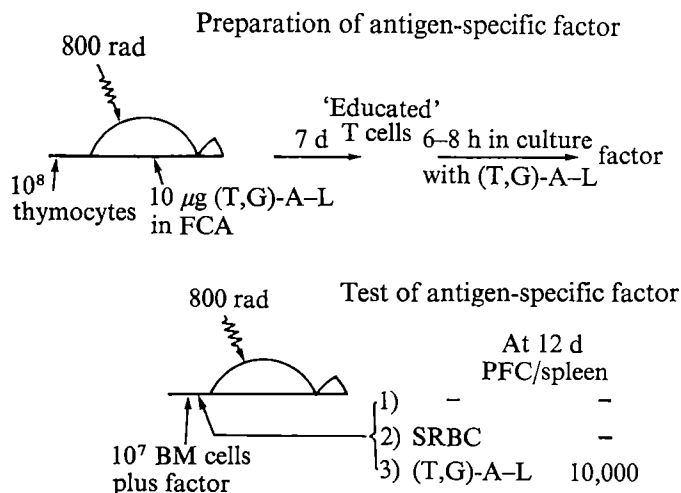
Test of antigen-specific factor


Fig. 1 Preparation and test of antigen-specific T-cell factor. The factor was prepared from mouse thymocytes which had been specifically primed or 'educated' to a synthetic polypeptide antigen such as (T,G)-A-L (poly (Tyr, Gln)-poly DL Ala-poly Lys)[17,18]. The educated mouse T cells were cultured for 6-8 h with antigen *in vitro*, then removed by centrifugation. The culture supernatant was the source of T cell factor. Its activity was assayed *in vivo* by transfer together with bone marrow cells and antigen, (T,G)-A-L, into a lethally irradiated recipient syngeneic with the bone marrow donor. 12-14 d later the spleens of these animals were found to contain specific antibody producing cells against (T,G)-A-L which can be enumerated as plaque-forming cells (PFC). Factor produced against (T,G)-A-L will not stimulate a response against an unrelated antigen such as sheep red cells (SRBC)[11].

does react with antisera raised against the major histocompatibility complex of the mouse (*H*-2), and using region-specific antisera we have mapped the genes involved to the *I* region of *H*-2[12,13]. These properties suggest that the T cell factor is the soluble expression of the T cell antigen receptor, and that the latter is coded for, at least in part, by the *I* region of *H*-2. Work from other laboratories supports this view. For example, a very similar antigen-specific molecule—though functionally suppressive—has been described by Tada and coworkers[14,15]; in addition, other T cell factors, though lacking antigen specificity, are also products of the *I* region, and probably closely related to the specific T cell factors[3,16].

Detection of B cell acceptor

Since the *I* region contains the *Ir* genes, the T cell factor is an obvious candidate for a product of these genes. Ability to produce the factor could therefore be used as an assay for *Ir*-gene function, and it would be predicted that in at least

Table 1 Responses of high responder and low responder bone marrow cells to (T,G)-A-L and T cell factor in F_1 recipients

T cell factor*	Bone marrow cells	Log_{10} PFC/spleen
No†	High responder (B10)	1 311
Yes	High responder (B10)	4 623
Yes	Low responder (B10.A)	1.462
Yes	F_1 (B10×B10.A)	4.724
	Standard error	0.184

*Factor specific for (T,G)-A-L was prepared in B10 BR (*H*-2^k) mice, low responders.

†Control: bone marrow cells transferred into irradiated recipients with antigen but without factor.

Responses given by 10^7 bone marrow cells when combined with 10 μg (T,G)-A-L) and the (T,G)-A-L specific T cell factor, and transferred into irradiated F_1 (B10×B10.A) recipients The bone marrow cells were of either high responder (B10), low responder (B10.A) or F_1 origin. Direct anti-(T,G)-A-L PFC measured in spleens of recipients 14 d after transfer. Results as log_{10} geometric means, standard error shown.

some cases, low responders would lack the ability to make the T-cell specific factor. When this was investigated using as antigen the synthetic polypeptide (T,G)-A-L[17,18], for which high and low responders are known it was found that a low responder strain (C3H/HeJ, *H*-2^k) produced the cooperative T cell factor as efficiently as high responders (C3H.SW, *H*-2^b). On the other hand, the factor, whether of high or of low responder origin, would only cooperate effectively with bone marrow cells of high responder origin[10]. From these experiments, it was concluded that the defect in low responders (of *H*-2^k haplotype) was expressed in the function of bone marrow cells rather than T cells. Table 1 shows an experiment to confirm this result. In this experiment, F_1 irradiated animals (B10×B10.A) were used as recipients for either high responder (B10 or F_1) or low responder (B10.A) bone marrow cells, which were transferred with the same T cell factor and antigen. It is seen that only the high responder bone marrow cells responded. This experiment also serves to rule out possible contributions of the irradiated recipients to the result, since identical F_1 (responder) recipients were used throughout.

In summary, *Ir* genes can be expressed in bone marrow cells, where they might function to receive the T cell product. It has already been predicted that B cells carry an 'acceptor' site for T cell factors[19], and it seems likely that this could be where the bone marrow defect is localised. A direct assay for

Table 2 Absorption of T cell factor by high and low responder bone marrow cells

No‡	—	1.261
Yes	—	4.230
Yes	High responder (B10)	1.799
Yes	Low responder (B10 A)	4.518
	Standard error	0.330

*Factor specific for (T,G)-A-L was prepared in B10.BR (*H*-2^k) mice.

†Factor sufficient for five recipients was absorbed with $5×10^7$ bone marrow cells.

‡Control: response in absence of factor

T cell factor for (T,G)-A-L was absorbed with either high or low responder bone marrow cells, and any remaining factor was mixed with F_1 (B10×B10 A) bone marrow cells and (T,G)-A-L and transferred into irradiated F_1 recipients. Direct PFC to (T,G)-A-L were measured 14 d later in the spleens of the recipients. Results as log_{10} geometric means.

the presence of an acceptor site on bone marrow cells is measurement of the ability of these cells to absorb T cell factor. As shown in Table 2, high responder (B10) bone marrow cells completely absorb the factor activity; low responder (B10.A) bone marrow cells, in contrast, do not absorb the factor at all. Similar experiments showed that the origin of the factor (that is, high or low responder) did not affect the result and that factor could also be absorbed in the absence of antigen. These experiments provide strong evidence for the existence of an acceptor in high responder, but not in certain low responder, bone marrow cells. Since bone marrow contains diverse cell types we have begun experiments with purified cell populations. Our preliminary results show that the acceptor is present on peripheral B cells (anti-θ-treated lymph node cells depleted of macrophages); the presence of an acceptor on macrophages and peripheral T cells has yet to be established. ·

It was clearly important for the interpretation of these experiments to show that the factor was taken up by B cells in a biologically meaningful way. This was demonstrated by transferring bone marrow cells which had adsorbed factor into lethally irradiated recipients with antigen but without further addition of factor. It was found that provided the adsorption

had occurred in the presence of the specific antigen, the bone marrow cells made a good response on transfer. Presumably the antigen was necessary to focus factor on to the antigen-specific B cells.

The absence of the acceptor site from the B cells of a low responder to (T,G)–A–L, indicated that *Ir* genes might directly code for the acceptor. Table 3 shows that functional binding of factor to the acceptor site can be blocked by anti-H-2 sera. Bone marrow cells of F_1 origin (high×low responder: B10× B10.A) were treated with anti-H-2 sera before absorbing factor in the presence of antigen. Anti-H-2[b] (that is, antibody to the high responder haplotype) prevented the bone marrow cells from functionally absorbing the factor, as measured by the response of the bone marrow cells in irradiated recipients, whereas anti-H-2[a] (the low responder haplotype) did not block the acceptor. Thus the acceptor seems to be coded for by genes in the *H-2* complex, and experiments are in progress to determine whether it is an *I*-region product, as predicted.

In summary, we have identified two products of the *H-2* complex, both probably coded by the *I* region, which are involved in T–B cell cooperation, namely the T cell factor and the B cell acceptor. As described above, there exist strains which are low responders to (T,G)–A–L because they lack the B cell acceptor. Do all non-responders share a B cell defect, or do some strains have T cell deficiencies which take the form of failure to make the specific cooperative factor? We have screened several strains for their ability to make T cell specific factor and for their B cell acceptor function. Table 4 summarises the results, and shows that while several strains have only B cell defects, one strain (B10.M, *H-2[f]*) has a 'pure' T cell defect, and another (SJL, *H-2[s]*) lacks both T and B cell function[32]. These findings make it very likely that two *Ir* genes are involved in control of the antibody response to (T,G)–A–L, one expressed in T cells, the other expressed in B cells. In order to confirm the two-gene hypothesis, we have studied the response of F_1s between non-responders of complementary type (that is, T or B cell deficient). As shown in Table 5, such F_1s are high responders. This complementation shows that almost certainly two genes affect the antibody response to specific antigens. Since in one F_1 combination (B10.BR×B10.M) the mice were congenic resistant and differ only at *H-2*, both the genes are located in the *H-2* complex, and from what has gone before, probably both in the *I-A* subregion. Backcross experiments are in progress to confirm this.

Taken together, the results described here provide strong evidence that two functionally distinct genes in the MHC determine the level of T-dependent immune responses by their effect on cell interaction. Other workers have found evidence for two *Ir* genes in the MHC by analysis of F_1 hybrids[20-22].

Table 4 Cellular defects in antibody response to (T,G)–A–L

H-2	Strain	Response	T cell factor	B cell response
b	B10, C3H.SW	High	Yes	Yes

j	I.St	Low	Yes	No
f	B10.M	Low	No	Yes
s	SJL	Low	No	No

Data from refs 10, 12, 32 and unpublished.

For example, Rüde and Günther found complementation in the response to (T,G)–A–L in rat F_1 hybrids[21], and more recently Benacerraf and colleagues have shown that two *Ir* genes control the response to the synthetic polypeptide GLPhe[11] in mice[22]. In the latter case, the genes were shown to map in different *I* subregions. It seems reasonable to expect that at least two MHC-linked genes will be found to determine the response levels to each thymus-dependent antigen. Our experiments take these findings further by defining the mode of action of the genes and their products. Thus one type of *Ir* gene codes for the antigen-specific T cell regulators of the immune response, and by inference, the T cell antigen recognition system. The second type of gene, by coding for an acceptor for the T cell regulators on lymphocytes determines the ultimate response of the cell to antigen (Fig. 2).

Model accounting for antigen specificity

We must now consider how the two genes would incorporate the antigen specificity which is the remarkable feature of the genetic control of the immune response. In the case of T cell defects in response an obvious possibility is that failure to respond to an antigen is due to the absence of the specific binding site for that antigen from the repertoire of T cell antigen receptors. The presence of *Ir* genes expressed in the B cell, however, requires a more complex explanation for the apparent antigen specificity of *Ir* gene control.

A model to account for the findings is as follows: (1) We propose that there must be several 'classes' of T cell factor,

Table 3 Blocking acceptor with anti-H-2 sera

*Specific for (T,G)–A–L, prepared in B10.D2 (*H-2[d]*) mice.
†5×10[7] bone marrow cells in 1 ml medium were heated with 0.1 ml undiluted antiserum for 30 min at 4 °C and then washed. Factor and (T,G)–A–L were then added and incubated with the cells for a further 30 min. The cells were again washed and then transferred into five irradiated F_1 recipients Antisera used were B10.D2 anti CWB (anti-H-2[b]) and B10 anti A/J (anti-H-2[a]).

T cell factor specific for (T,G)–A–L was absorbed, in the presence of (T,G)–A–L, on to either normal or antiserum-treated F_1 (B10× B10.A) bone marrow cells. The cells were then transferred, without further addition of factor, into irradiated F_1 recipients. The direct anti-(T,G)–A–L PFC responses in the spleens of the recipients were measured 12 d later. Results as log$_{10}$ geometric means.

Fig. 2 Cell interaction in the antibody response Model showing the possible relationship between T cell receptor, specific T cell factor and B cell acceptor in cell cooperation and a mechanism of B cell triggering. 'Ia' refers to the antigenic determinants carried by the T cell factor detected by antisera raised against the *I* region. The *Ir* genes are believed to code for the T cell receptor, the T cell factor and the B cell acceptor

analogous in a sense to the classes of immunoglobulin and that for each factor class there exists a corresponding acceptor. The genes for a T cell factor class and the corresponding acceptor for that class comprise a 'set'. Note that the T factor is assumed to be clonally expressed, whereas each B cell would carry all classes of acceptor site. (2) Within each set there would be genes which contribute to the antigen-binding sites carried by that class of factor. Taking again the analogy with immunoglobulin genes, each set would contain a number of 'variable' (V) genes which could become associated with the 'constant' (C) gene for the T factor of that set (Fig. 3). (3) An important point is that the V genes of any one set will only code for part of the total binding site repertoire of T cell factors. In this way there will be antigens which will only react with the binding sites of one set, although there will be other antigens for which several sets are available. (4) The loss of a B cell acceptor for one class of T factor will render the B cell incapable of response to factor of that class, and thus to any antigen which is dependent solely on that set for cell cooperation. This would predict that all antigens which are restricted to that defective set would fail to give responses. (5) Two types of T cell defect are possible, namely (a) a defect in a specific antigen binding site, as already mentioned, and (b) a defect in the constant region of the T cell factor, leading to the effective inactivation of the entire set. (6) A consequence of the model is that 'Ir-gene' control will only be noticeable for antigens which are restricted to the binding sites of one set. This explains the well-known observation that genetic control is in general only observed for antigens where a limited number of determinants are presented to the
system, for exampe synthetic polypeptides, proteins in limiting dose, and alloantigens[1]. (7) The different patterns of response which antigens show in different strains[1-3,23], arise in part because of the different genetic causes of low responsiveness. Furthermore, there is the possibility of genetic rearrangements, so that the genes comprising each set can vary between strains.

Although this model explains a great many of the phenomena associated with Ir genes, there are certain observations which require further discussion. For example, while we have shown that T cell factor can be produced to (T,G)–A–L in certain low responder strains, these same strains (notably H-2^k) lack other specific T cell-dependent activities such as delayed hypersensitivity (Davies and Shearer, personal communication), and proliferation of T cells in response to antigen in vivo[24], and in vitro[25]. This dichotomy could be explained if T cell–T cell interaction were necessary for the generation of effector T cells, and if this interaction took place by the same molecular mechanism as T cell–B cell cooperation. Alternatively, suppressor T cells may be generated in situations where low response results from an acceptor defect[26,27]. A further problem arises from the response to (T,G)–A–L in tetraparental mice constructed from high responder (H-2^k) parents, where low responder B cells produced antibody to (T,G)–A–L[28]. This is at first sight difficult to reconcile with our demonstration of an acceptor defect on H-2^k B cells. But it may be that conditions in the responding tetraparental create an environment in which the acceptor defect can be bypassed. Alternatively strains nominally of the same H-2 haplotype may have undergone rearrangement or mutation of genes in the I region. The locus of unresponsiveness in the animals used to contruct the tetraparentals would have to be determined to distinguish these possibilities.

Finally, the emerging significance of the I-region products, not only in genetic control, cell cooperation and factor production, but also in mixed lymphocyte reaction[29], graft-*versus*-host response[30], immunological enhancement[31], and so on, suggests that these phenomena may all be reflections of the same molecular structures.

Fig. 3 Immune response genes of the H-2 complex. Schematic representation of the possible arrangement of genes in 'sets' in the I region of H-2 Within each set are genes coding for the binding site of the T cell receptor and factors 'V genes', for the 'constant' region of the receptor and factors 'C genes', and for the acceptor

letters to nature

X-ray observations of Cyg X-1 with ANS

FROM May 1 to May 8, 1975, Cyg X-1 was observed with the instruments on board, the Astronomical Netherlands Satellite (ANS). We report here the results of the measurements performed with soft and hard X-ray detectors of the Space Research Laboratory in Utrecht and the Center for Astrophysics in Cambridge, USA. Cyg X-1 underwent an upward transition in its intensity[1], that seems to be the inverse of the downward transition seen by Uhuru in April 1971. The bulk of the increase occurs at low energy: between 1 and 2 keV, the intensity increased by a factor of 10 over the November 1974 intensity observed by ANS, while above 8 keV there is no significant change.

The Utrecht experiment consists of two detectors. A 1.7 μm titanium window proportional counter of 45.0 cm^2 effective area collimated to a field of view of 36'×90' (FWHM) is sensitive in the energy range 0.35–0.45 keV and 1–7 keV, divided over 6 pulse height channels. The second instrument, a parabolic reflector with a projected area of 144 cm^2, has in its focus a small-area counter with a window of 3.6 μm polypropylene. The field of view is a 34' circle. A full description of the instrument is given in ref. 2.

The relevant portion of the Cambridge experiment consists of 50 μm beryllium window proportional counters of 50 cm^2 effective area collimated to a field of view of 10'×3° (FWHM) sensitive in the energy range 1.3–30 keV divided into 15 energy channels[3].

The light curves of Cyg X-1, as observed in the medium energy range (1–7 keV) of the Utrecht detector and in the 1.3–7 keV window of the Cambridge detector, are presented in Fig. 1. The source is observed to be in a high intensity state, similar to the one observed[4] before the transition in April 1971. The count rate has increased by a factor of 8–10 in the Utrecht detector and a factor of about 4 in the Cambridge detector compared with the observations on Cyg X-1 made with ANS in November 1974 (our unpublished work with W. Forman, C. Jones and

Y. Tanaka). The count rate in the first measurement on May 1 is at the lowest point for both detectors, at 80 counts s^{-1} and 58 counts s^{-1} respectively, and rises to 100 counts s^{-1} (80 counts s^{-1}) on May 3, suggesting that the source is in its last stage of the actual transition. After May 3, the intensity averages above 100 counts s^{-1} (80 counts s^{-1}) with excursions up to 160 counts s^{-1} (130 counts s^{-1}). The spectrum is in all data very steep, similar to the one observed[4] before April 1971. In fitting the measured pulse height spectrum with a source spectrum of the form

$$dF/dE = AE^{-\alpha}\exp(-\sigma n_H) \ \text{keV}(\text{cm}^2 \text{ s keV})^{-1}$$

where σ is the Brown and Gould[5] interstellar absorption and E the photon energy in keV, we find a best fit for the first measurement on May 1 of $\alpha = 2.6 \pm 0.2$ and n_H (equivalent) $= 7^{+3}_{-1} \times 10^{21}$ atoms cm^{-2}. In general, all the measurements fit with a power-law energy index range in the narrow band of 2.2–2.8, with an absorption of $8^{+4}_{-2} \times 10^{21}$ atoms cm^{-2}, whereas in the November 1974 data the spectrum was as flat as $\alpha = 0.4$, changing on a time scale of minutes to $\alpha = -0.5$ (a positive slope). The beryllium window counters also show little if any change in the intensity and spectrum above 8 keV, as compared to the ANS observations of November 1974.

The polypropylene counter–parabolic mirror combination has a transmission window between 0.2 and 0.28 keV and a side lobe between 0.4 and 0.7 keV. The pulse height discriminator levels are optimised for 0.2 to 0.28 keV, and in view of detector resolution set to 0 13 and 0.41 keV. The small efficiency at 0.4–0.7 keV is due to the finite counter resolution in the 0.13–0.41 keV pulse height interval. By integrating the Cyg X-1 signal in the parabolic section over 1,600 s, we observe a count rate of 0.38±0.04 counts s^{-1}, which in view of the large column density of interstellar matter to the source must be due to the high energy end of the detector window. The interstellar absorption for 7×10^{21} atoms cm^{-2}, assuming Brown and Gould[5]
Fig. 1 The preliminary light curve of Cyg X-1 between May 1 and May 8, 1975. Black dots indicate the count rate of the Utrecht medium energy detector SXX (1–7 keV), open triangles are the count rates of the Cambridge hard X-ray detectors HXX (1.3–30 keV). The average count rate during the November 1974 observations are also indicated. Bars indicated typical excursions in intensity during observations of a few minutes. Marker on date axis indicates 0000 UT for indicated day.
Fig. 2 Spectrum of Cyg X-1. The left-hand side shows the flux at Earth for a typical set of best fit parameters. O and Ne mark the absorption edges. The right-hand side shows this spectrum convolved with the detector response of the two Utrecht detectors and the observed count rates in the different pulse height channels. The signal in the polypropylene counter (*a*) is integrated over a longer time interval than that of the Ti counter (*b*).

abundances, is 3.3 mean free paths just below the oxygen absorption edge of 0.53 keV, and 19 mean free paths at 0.28 keV. The ultraviolet flux of the ninth magnitude BOI stellar companion of Cyg X-1 is three orders of magnitude too low to explain the soft flux by contamination of the ultraviolet flux, both from the theoretical point of view and from the measured ultraviolet spectrum[6]. The detected flux in the soft X-ray counter is entirely consistent with an assumed source spectrum with power law (energy) index of 2 5 and interstellar absorption of 7×10^{21} atoms cm^{-2}. The expected count rate for this spectrum is $0.28 \ s^{-1}$. This spectrum is presented in Fig. 2, together with the measured flux and the spectrum convolved with the response of the two detectors. With this spectrum the source intensity at 0 50 keV then corresponds to 13 ± 3 photons $cm^{-2} \ s^{-1} \ keV^{-1}$ and the power spectrum is valid over the entire range from 0.5 to 6 keV (ref. 7).

The intensity and spectrum of X radiation from Cyg X-1 observed by the ANS instruments are now dramatically different from those observed by the same instruments during November 1974. The present data, both the high intensity and the changed spectra, are consistent with what was reported by Uhuru for the 'high' state of 1970–71. For this reason, and because this high level has persisted for about six days as we see it, we conclude that Cyg X-1 has reverted to its high state. Our data also suggest that the transition was in progress when we began observing on May 1.

Several descriptions have been put forward to explain the observed low and high intensity states of Cyg X-1 on the basis of accretion disk models[8]. In these models the flux above 10 keV originates in the optically thin inner disk, and the flux below 10 keV in the optically thick region immediately surrounding the inner disk. The transition could be due to a change in accretion rate or to the switch on and off of a secular (Lightman and Erdlich) instability in the inner region of the accretion disk[9] where the disk could become spatially thick and optically thin wherever radiation pressure dominates gas pressure. Thorne and Price[8] make various predictions for the photon energy E_{max} at which the source spectrum exhibits a maximum.

From the spectrum presented in this paper $E_{max} < 0.5$ keV suggesting, on the basis of the qualitative model of Thorne and Price, that the transition is triggered by a change in

the accretion rate in a disk model where the optically thin region is indeed extended (Lightman–Erdlich instability operative).

The power spectrum of Cyg X-1 integrated from 0.5 to 6 keV leads to an intrinsic luminosity at 2.5 kpc ranging between 7.0×10^{37} and 9.6×10^{37} erg s^{-1}.

Extended X-ray, optical and radio measurements are now in progress and may help clarify the nature of this transition. On May 9 the radio emission was several times higher than at any time in the previous four years[10]. This is in contrast to the behaviour during the previous high state when Cyg X-1 was not seen in radio. Also, Bolton[11] has not seen any spectroscopic changes in the optical emission.

Observations of a new transition in the emission from Cyg X-1

THE all-sky X-ray monitor aboard Ariel V is a pinhole camera sensitive to X rays in the energy range 3–6 keV. It has an effective area of 0.6 cm^2 with a duty cycle of $\sim 1 \%$ for a given source, and monitors more than 3π of the celestial sphere each orbit[1].

Following the first report[2] that the emission from Cyg X-1 had increased, we used data from the all-sky monitor to establish that a sudden transition had occurred on April 22, 1975, 9 d before the initial observation from ANS. Cyg X-1 has been observed almost continuously since $\sim$ November 1, 1974, by this experiment, and has been relatively constant in apparent magnitude until the reported effect. Its pre-transition average intensity was 0.5 ± 0.1 efficiency-corrected photons $cm^{-2} \ s^{-1}$ in the energy range 3–6 keV, where the 20% error is the estimated absolute calibration uncertainty. During the > 5 months before the transition, the average daily intensity was
Fig. 1 Daily average intensity of Cyg X-1 for 50 d. The constancy of the intensity before day 112 is representative of the source (as measured by this experiment) since November 1974.

rarely measured as high as 0.7 $cm^{-2} s^{-1}$. The Crab Nebula intensity in the same units is 1.4 $cm^{-2} s^{-1}$.

Daily averages between March 15, 1975 (day 74), and May 3, 1975 (day 123), are displayed in Fig. 1. No Cyg X-1 data were taken during days 101 and 102, but the data taken up to day 100 are representative of the behaviour of Cyg X-1 since the onset of experimental operation. From days 103–123 Cyg X-1 was located at approximately the same spacecraft latitude, so that no intensity changes may be ascribed to systematic errors in the data analysis. On day 123 the satellite was reoriented to allow the four Ariel-V experiments which view along the spin axis to observe Cyg X-1, placing it outside the field of view of this experiment.

The data after day 103 are shown with an approximately half-day resolution in Fig. 2. The natural resolution of the experiment is one satellite orbit ($\sim$100 min), but the statistical errors on some data points then become more than half as large as the magnitudes, so that we have not attempted to present finer resolution than that shown in Fig. 2.

Clearly, the rise above 1 $cm^{-2} s^{-1}$ during the latter half of day 112 is real, as the intensity continues to rise to more than three

Fig. 2 Intensity measured from Cyg X-1 over approximately half-day accumulation times. The source is no longer in the field of view of the experiment after day 123 (May 3).
times the pre-transition average value during the first half of day 113. The intensity then seems to oscillate between $\sim$1 and $\sim$2 $cm^{-2} s^{-1}$ with a time scale of several days until it passes out of our field of view on day 123 (May 3, 1975). As the experiment has no spectral resolution, we cannot comment on any spectral change which may have accompanied the intensity transition. The 3–6 keV acceptance window is relatively insensitive to spectral shape, however, so that the indicated intensities in the 3–6 keV band should be correct whether or not the spectrum changes.

Cyg X-1 has remained remarkably constant in intensity and spectrum[3] since the "transition" in 1971 (ref. 4). Before 1971, the intensity was extremely variable, and the spectrum was always softer than that measured afterwards. Whether or not the effect reported here represents a long term return to its pretransition state is something which this experiment will be able to monitor in the future.

Millisecond temporal structure in the emission from this source has previously been measured only by large area rocket-borne experiments[5], and the present intensity increase should now make possible its study with instruments of smaller area mounted on various satellites. Ariel V and Copernicus measurements of the X-ray variability of Cyg X-1

THE collimated proportional counter (experiment C of MSSL) on Ariel V viewed Cyg X-1 in 1975 from May 3 1400 UT until May 15 1000 UT. We report here observations of the intensity and spectrum obtained with an integration time of $\sim$30 min. They show that, at the beginning of this period, Cyg X-1 was more intense, had a steeper spectrum and was generally more active than has been observed during the past 2½ yr by Copernicus[1,2]. Towards the end of the period the source seemed to be returning to its lower state.

Figure 1 shows the 1.5–15 keV and the 2–6 keV fluxes from Cyg X-1 during the Ariel V observations. The dominant errors in the values of intensity are due to uncertainty in the total integration time, rather than statistical errors, and it is the total $\pm 1\sigma$ errors which are shown on the two intensity light curves. Also plotted against time is the photon index of the power law spectrum obtained by fitting the data in the 1.5–15 keV energy range. The values observed (with Ariel V) during a brief look in October 1974 are also indicated.

The intensity and spectral index were indicative of a high state[4] at the start of the observation on May 3, 2 d after the onset of the low–high transition reported[3] from ANS. The source remained in the high state until May 9 or 10; it then began to recover its low state values represented by the October 1974 data. The transition back to

Table 1	2-10 keV X-ray observations of Cyg X-1

May 1975	Ariel V	This paper	-4.2 ± 0.2 to -2.1 ± 0.2	High, then approaching low
May 1975	Copernicus	This paper	-2.1 ± 0.2	Approaching low

the low state was not complete when the satellite moved on in its observing programme on May 15.

Figure 2 shows the measured spectrum and best fit power laws of two typical orbits at the beginning and end of this run of data. The spectrum of May 6 shows an excess of high energy X rays above the power law spectrum, as indicated by the higher value of χ^2.

The high and low states seen by Ariel V are similar in intensity and spectral index to those reported from Uhuru[4] before and after the down transition about April 1, 1971. The high energy excess in Fig. 2a (in the high state) is also seen in the Uhuru data before this transition, but the Ariel V spectrum does not have the sharp change of slope reported from Uhuru[4].

Copernicus has observed Cyg X-1 on ten occasions between November 6, 1972, and May 12, 1975, of which the first seven are summarised by Mason et al.[2]. A measurement of spectral index on May 12, 1975, by Copernicus agrees with the value -2.1 ± 0.2 measured then by Ariel V. On all the nine previous occasions the slope was significantly different at -1.6 ± 0.1.

The implication is that Cyg X-1 was in its low state from April 1, 1971, until May 1, 1975, and in a high state for about 20 d thereafter. (If, however, 20–30 d is a typical duration for the high state, such flashes could slip between gaps in the Copernicus coverage, which are up to 180 d long.)

Table 1 lists spectral indices in the energy range 2–10 keV of Cyg X-1 taken from the literature. The first measurement of a spectral index considerably different from $\alpha = -1.6$ was reported by Bleach et al.[10] on September 21, 1970. Subsequently data from Uhuru[4] also yielded a departure from the usual value of the spectral index, as did a measurement by Cruise[11], made on November 11, 1970, which showed $\alpha = -2.8$. It is possible that this high state, characterised by enhanced emission in the 2–10 keV region, together with a steeper and more variable spectrum, lasted at least six months until the down transition reported by Tananbaum et al.[4]. It is improbable but not impossible for an up state of this duration to have occurred during the Copernicus measurements without having been detected. It seems that the low state, characterised by the power law spectral index stable at -1.6, is the usual state of Cyg X-1 in which the source remains for about 90% of the time.

We have searched the Copernicus data taken between 1972 and 1975 for any systematic change in X-ray behaviour which might herald a transition. One possibility is a variation in the orbital phase at which absorption events are seen[2]. The data of Mason et al.[2] suggest a systematic change in phase of the absorption events on a time scale of a few years (their Fig. 3), and this trend is confirmed by two further observations: Li and Clark[12] observed, with OSO 7, an absorption event in June 1973 at
Fig. 1 The X-ray intensity and spectral index for the May 1975 observations with Ariel V.

Fig. 2 Power-law spectra obtained on two representative orbits. *a*, May 6; *b*, May 13. For curve *a* (orbit 3080), $N(E) \propto E^{-3.6 \pm 0.1}$; curve *b* (orbit 3191), $N(E) \propto E^{2.0 \pm 0.05}$. χ^2 per degree of freedom is 4.7 for May 6 and 1.8 for May 13.

a phase of +0.053 using the ephemeris of ref. 2; and in October 1974 a Copernicus observation revealed an event at phase −0.12. The project orbital phases of the events at the time of the 1971 and 1975 transitions are +0.20±0.02 and −0.18±0.01 respectively, which, within the errors, is symmetrical about the line of centres of the binary system.

Without a knowledge of the behaviour of the absorption events following the May 1975 transition, we can only draw attention to this coincidence. But if the absorption events are, as suggested in ref. 2, a manifestation of the gas flow which powers the X-ray source, a correlation between their behaviour and periods of activity is not unreasonable, since changes in the accretion process are a possible trigger mechanism for the transition[13].

This hypothesis does predict that the phase or nature of the absorption events will change significantly following the May 1975 outburst.

Another major change in the radio source associated with Cyg X-1

THE sudden appearance[1,2] of a faint radio source inside the probable position region for the X-ray source Cyg X-1 was associated with major changes in the X-ray emission observed[3] during the period February–May 1971. This coincidence established a probable association with the X-ray source. The accurate position of the radio source led to an identification[2,4] with the bright, blue star HDE226868. Subsequent optical investigations have established[5,6] this object to be a binary system with a massive, invisible component that may be a black hole.

Since 1971, no major changes in the Cyg X-1 X-ray and radio source had been reported until the spring of 1975.

We now report further observations of the Cyg X-1 radio source, the most recent of which were made after learning[7] that Cyg X-1 had undergone another major change in X-ray state in, or before, early May 1975. The radio observations were made with the NRAO interferometer at 2,695 and 8,085 MHz and are shown in three parts in Fig. 1. The first part has been published previously[8], but is shown again for completeness and comparison. It shows the 1971 X-ray transition in the 2–6 keV range and the initial appearance of the radio source between March 22 and March 31, 1971, followed by the radio history of the source until October 1972. The second part shows observations between March 1973 and March 1975, which have not been published before. The last part shows observations taken during May 1975 after learning of the recent change in X-ray state[7].

An extensive discussion of the 1971–1972 radio data has been given by Hjellming[8]. The major point of interest is the approximate mean level of 0.015 Jy maintained by the radio source at both 2,695 and 8,085 MHz during the period March 1971 to March 1975. This level is shown by dashed lines in Fig. 1. There are some clear fluctuations about this norm, particularly during extensive observations in October 1972, but a mean level of 0.015 Jy was maintained by the radio source over a time span of four years. The observations of Cyg X-1 at 1,415 MHz by Braes and Miley[2,9] also showed a mean flux level of 0.015 MHz. Thus one of the major characteristics of the Cyg X-1 radio source between March 31, 1971, and March 1975 is a flat radio spectrum, that is, a spectral index of 0.

The Cyg X-1 radio observations on May 9, 1975, are shown on a greatly expanded scale in Fig. 1, because, in addition to the fact that the mean flux density for this day was 0.035 Jy at 8,085 MHz, considerably above the previous norm, the variations from a peak level of 0.045 Jy to a lower level of 0.030 Jy over a period of 5 h on May 9 are real. Subsequent sampling of the radio source between May 10 and May 20 is shown in Fig. 1, plotted on a time scale intermediate between that of the May 9 data and the earlier data.

The mean daily levels of Cyg X-1 during the period May 9–20, 1975, are 0.031 Jy at 8,085 MHz, and 0.002 Jy at 2,695 MHz These levels clearly represent a new state for the radio source. A particularly interesting feature of the new state is the change of the mean spectral index from 0 to 0.31. This means that if the radio emission mechanism is thermal, the source has become slightly optically thick
Fig. 1 Radio observations of Cyg X–1 (HDE226868) at 2,695 and 8,085 MHz are plotted as a function of time for the period between February 1971 and May 1975. Also shown is the change in X-ray level in the 2–6 keV energy range during February–April 1971. Note that the time scale for the abscissa is not linear and that different time scales are used in plotting the May 1975 observations.

with an optical depth of 0.17 at 8,085 MHz; however, if the radio emission mechanism is non-thermal, the source is self-absorbed.

Can soft γ-ray bursts be emitted by accreting black holes?

THERE are many models for the observed γ-ray bursts[1], but none has proved entirely satisfactory. Here we suggest another possible model: that the γ rays are produced by inverse Compton processes occurring deep in the ergosphere of a fast rotating, accreting, black hole. At the time of burst, plasma, which has an optical depth of the order of the relevant gravitational distances, emerges near the horizon due to an instability, and free falling photons, which are produced by viscous processes in an accretion disk further away, are being scattered off it. In this model the black hole itself is probably a member of a binary system, and, depending on its steady-state accretion rate, may or may not be observable as an X-ray source.

With Katz, we have shown[2] that photons, which free-fall into a Kerr horizon to be Compton scattered by tangentially moving electrons, can acquire very high energies by the Penrose mechanism. The scattered electrons share their negative energy with the protons; thus, the excess photon energy may be supplied mainly by plasma gravitational energy. When the scattered photons escape to infinity, their energies at infinity do not exceed a few $m_e c^2$. We have calculated numerically overall energy spectra for several realistic scenarios of plasmas with

turning points close to the horizon, by the Monte Carlo procedure. Details will be published elsewhere; here we report briefly the emerging qualitative picture.

The maximum energy obtained in the conversion of free-falling X-ray photons into γ rays, increases as the collision point approaches r_{mb}, and can become as high as a few electron masses for $a/M \to 1$. For a canonical black hole[3] ($a/M = 0.998$), and for an X-ray photon of 10 keV falling in radially, energies as great as 600 keV can be reached; with a 50 keV photon falling in radially, energies reach 900 keV. This maximum energy increases when collisions of outgoing photons are considered and, at any rate, increases rapidly as a/M grows above its canonical value.

A small number of collisions help to increase the overall efficiencies by directing additional scattered photons outwards. But when many collisions occur, the photons merely become "thermalised", and the possibility of using free-fall no longer exists. The maximum efficiency was of the order of 10% or higher in the examples considered, and one may also expect a certain anisotropy in the emitted spectra. All our spectra seem to stabilise at spectra similar to those observed[4] when collisions occur deep enough and rotation is fast enough.

The inner disk region is secularly unstable[6,7] and is, therefore, a likely location of matter flow instabilities. The time scale for these instabilities is of the order of a few seconds or less, whereas the time scale for fluctuations around and inside r_{ms} is of the order of a few milliseconds. For accretion rates which are not larger than $10^{-9} M_\odot$ yr^{-1}, and for canonical black holes with masses ~ 1–$10 M_\odot$, the number of (proper) optical depths for high energy photons in the region between r_{ph} and r_{ms} is normally less than one. The suggested γ-ray production mechanism will only be effective for a depth of 1–3 optical paths, which is not an inconceivable number for instabilities in such disks, but is an unlikely number for steady-state flow. This is also in agreement with recent disk structure models (S. L. Shapiro, A. P. Lightman and D. M. Eardly, unpublished and A. P. Lightman, personal communication.)

The initial photons could come from the steady-state flux of the disk or, which seems more likely, from the event itself; one could imagine a sudden burst of matter flow on the companion star[8] to dump a lot of material on the disk, thus producing both a large number of X-ray photons and the necessary deep ergo-sphere plasma flow. The occurrence of softer, and longer lasting, X-ray bursts, on which some of the γ-ray events seem to ride[9], is certainly not inconsistent with such an interpretation. The Vela satellites' γ-ray burst 71–2 (ref. 10), which seems to have come from the general direction of Cyg X-1, occurred close to a remarkable transition in that X-ray source[5]. It is tempting to associate that burst with a disk instability, which is, in turn,

also indicated by the X-ray and radio data (ref. 11 and S. L. Shapiro, A. P. Lightman and D. M. Eardly, unpublished).

We thank J. Katz for discussions.

Mother and baby paradox

THE 'twin paradox' of relativity theory describes the difference in the elapsed time between the twin who stays at home and the one who goes on a space flight and returns. No genuine paradox is involved; elapsed time is not in general independent of the state of motion. In this case the difference in the elapsed time is related to a difference in the (locally measurable) acceleration histories of the twins; the space traveller must suffer an acceleration, however brief, in order to return.

But no paradox is involved, even if there is no locally measurable effect to distinguish the two timekeepers. General relativity provides such possibilities, one of which I describe here.

A mother, desiring her baby to remain young for as long as possible, decided on the following plan of action. Each night, when the baby was asleep, she went out and collected masses from afar, symmetrically, and arranged them in a spherical shell around the baby's crib (herself staying outside and some distance away from the completed shell). The baby's sleep was not disturbed, no acceleration being measurable inside the shell. In the morning before the baby woke up, she dismantled the shell and stored the masses again far away. Doing this carefully, with spherical symmetry, again no acceleration could be felt by the baby. But, in the 12-h period of the night experienced by the mother, the baby had aged only 12 h× $(1-GM/Rc^2)$ (for small values of GM/Rc^2, where M and R refer to the mass and radius of the shell, and G and c are the gravitational constant and speed of light respectively). In the daytime the components of the shell were stored so far apart that the large value of R made the value of GM/Rc^2 negligibly small.

By this procedure the mother's and her baby's timekeeping were caused to be different; yet, unlike the case of the 'twin paradox' of special relativity, without any necessity for a different acceleration history.

Trapped helium and argon and the formation of the atmosphere by degassing

I REPORT here some radiogenic ^{4}He and ^{40}Ar data measured in the glass margins of deep sea pillow basalts, and comment on their applicability to discussions of formation of the Earth's atmosphere by degassing from a solid Earth.

Discussions of such degassing generally assume either catastrophic or continuous degassing (see refs 1, 2 and references therein). In fact, there is no reason why these two sets of models should be considered to be mutually exclusive. The history of the Earth may include both a catastrophic event with an associated 'big burp', and later continuous degassing.

Ozima and Kudo[2] and Ozima[3] have presented calculations which indicate the evolution of the terrestrial ^{40}Ar/^{36}Ar ratio as a function of time, in either catastrophic or continuous degassing models of atmospheric formation. In particular, Ozima[3] has shown that the present ^{40}Ar/^{36}Ar ratio in the mantle is a sensitive indicator of the validity of the catastrophic model. In such models, the degassing is defined by any two of these four quantities: The time of degassing; the fraction of Ar degassed; the K content of the Earth; the present value of the ^{40}Ar/^{36}Ar ratio within the Earth. Ozima showed sets of graphical solutions for these quantities which satisfy the total Ar abundance and the present atmospheric ratio of 295.5.

The rare gases found in deep sea basaltic glasses are clearly those trapped within the rock on its eruption[4-6], due to the high hydrostatic pressures and rapid chilling, and as such represent mantle-ambient gases. A characteristic of those trapped gases is the presence of "excess" radiogenic ^{4}He and ^{40}Ar, in amounts greater than can be accounted for by the decay of U, Th and K subsequent to their eruption[4-7]. Similar "excess" ^{40}Ar contents have been measured in ultramafic intrusives[8] and in continental rock, but their origin is not as clear.

Ozima therefore accepted the ^{40}Ar/^{36}Ar trapped in submarine basalts as representing the isotopic ratio in the upper mantle; the published ratio available to him, ~1,000, could not be reconciled with a catastrophic degassing model of the Earth's atmosphere without the assumption of an unacceptably high K content[3]. He noted, however, following Schwartzman[16], that if the ultramafic values for this ratio (~10,000) were indicative of mantle gases, then the catastrophic model could not be ruled out. The ^{40}Ar/^{36}Ar values shown here in Table 1, measured in the glassy margins of deep sea basalts from both the Atlantic and Pacific Oceans, on both ridge and non-ridge samples, reach values as great as ~15,000. If these values are accepted, Ozima's argument against the catastrophic model must be relinquished. The argument can be replaced, however, with one based on the ^{4}He/^{40}Ar data of Table 1.

Schwartzman predicted a ^{4}He/^{40}Ar ratio in the present-day mantle of between 1.36 and 2.23, depending on the

Table 1 ^{4}He, ^{40}Ar, and ^{36}Ar data in glassy margins of deep sea basalts. The rocks are described in refs 4 and 17. All units are 10^{-8} s.c.c. g^{-1}. The ^{40}Ar reported is total measured ^{40}Ar; correcting for atmospheric contamination does not change the ^{4}He/^{40}Ar results significantly

Fig. 1 $^4He/^{40}Ar$ ratio as a function of elapsed time in a closed system, for various values of the K/U and Th/U ratios.

a,   Th/U = 3.6 ⎫
                ⎬ K/U = 1.5×10^3
     Th/U = 2   ⎭
b,   Th/U = 3.6 ⎫
                ⎬ K/U = 3×10^3
     Th/U = 2   ⎭
c,   Th/U = 3.6 ⎫
                ⎬ K/U = 10^4
     Th/U = 2   ⎭

Th/U ratio, for a catastrophic degassing model with very early degassing[1]. He noted that this is in agreement with a ratio estimated for the former environment of lherzolite nodules from Hawaiian nepheline mellilite basalt[9], and pointed out that greater values (2–10) found by Wasserburg *et al.*[10] in volcanic gases might well be due to preferential leaking of ^4He from wall rocks. But some of the values shown here (Table 1) are much too great for such a model, and the preferential leaking argument is much weaker for sub-oceanic mantle sources than for the terrestrial volcanic emanations of Wasserburg *et al.* Since the gas trapping mechanism cannot be 100% efficient, and since in any gas loss ^4He will be lost preferentially to ^{40}Ar, the largest $^4He/^{40}Ar$ ratios reported here are minimum values for the magma-ambient ratios. These values, 15–18, cannot be accounted for at all if the magmatic K/U ratio is similar to the crustal value of 10^4, even less if the ratio is chondritic $(3-6 \times 10^4)$, as seen in Fig 1. Thus the data rule out all models which ascribe the terrestrial atmosphere to any type of degassing of a mantle which is chondritic or crustal with respect to the K/U ratio.

K/U ratios measured on ultramafic rocks lead to an estimated mantle value of $\sim 3 \times 10^3$ (refs 11–14). Assuming this value gives maximum $^4He/^{40}Ar$ values of 15–20 (Fig. 1), but only for an age $\lesssim 10^9$ yr; for a catastrophic degassing model this is the age of the catastrophe, and is much too young The catastrophe is normally identified with formation of the Earth's core, and must have occurred at least within the first 10^9 yr of Earth history; so the age must be $>3.5 \times 10^9$. This necessitates a K/U ratio in the source region $<1.5 \times 10^3$ Such a value is barely within the widest limits set by K/U measurements on ultramafic rocks · 1×10^3–10×10^3 (ref. 12), 1×10^3–5×10^3 (ref. 13). An even smaller K/U ratio would be necessary if core formation (and an associated 'big burp') is to have generated the atmosphere within the first 100 Myr of Earth history, as suggested by Oversby and Ringwood[18].

These data do not suggest that catastrophic core formation, with or without an associated degassing 'burp', could not have occurred. They do suggest that the mantle has not been a closed system with respect to Ar and He

since any such postulated event, and therefore that significant later or continuous degassing from the interior Earth must have occurred The relative contributions to our present atmosphere from a possible early catastrophic event and the necessary later degassing have yet to be worked out.

Further data on $^4He/^{40}Ar$ ratios in more submarine glasses of wider geographic location and of varying magmatic origins, and on K/U ratios in a wider variety of possible mantle materials, should settle the question conclusively.

Geodynamic implications of transverse folding in the Western Alps for the Alpine fold belt

LARGE amplitude translations towards the external parts of the Alpine arc are still considered as the major feature of Alpine tectonics[1-5]. More recent approaches, inspired by concepts of global tectonics[6-8], have led to the development of new models, none of which however accounts for the widespread distribution of early transverse folds which in general are thought to have been formed either before[9] or later [10-13] than the overthrusting, and are considered to be minor structures. New data on the variations in strike of both transverse and longitudinal folds have been gathered over wide areas of the Alps between Savone and the Simplon Pass. The results indicate that in the whole Pennine Zone as well as part of the external zone only two important successive phases of folding have occurred, the trends of which are completely different. Here I am concerned with the 'initial transverse phase' or 'main Alpine phase' of deformation.

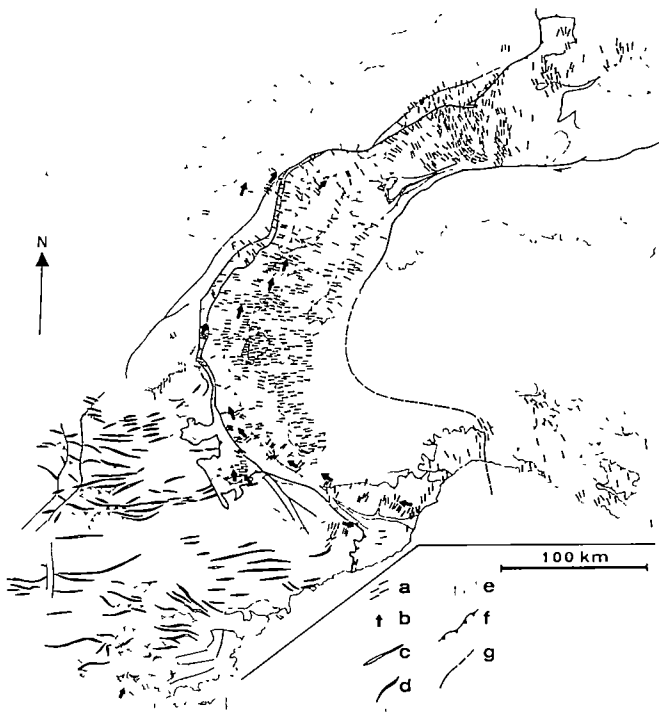
The axes of folds generated during the early Alpine deformation, in each of the internal structural zones, now lie roughly in a radial position with respect to the alpine arc (Fig. 1). The S_1 primary cleavage is everywhere related to this phase of deformation The following domains have been distinguished: (1) a zone of incipient slaty cleavage defined by illite-chlorite, for example in the uppermost overthrust sheets of the Briançonnais zone; (2) a zone of flow cleavage parallel to the axial planes of transverse isoclinal folds, for example in the Mesozoic cover of Vanoise[11] or in the Piemontese schistes lustrés of the lawsonite-glaucophane facies[14]; (3) a zone of foliation defined by the preferred orientation of phengite, glaucophane, zoisite, for example in the internal crystalline massifs and Piemontese


Fig. 1 Trend of transverse folds of the F_1 phase of Alpine deformation (post–Lower Eocene). In the Briançonnais and Grand St Bernard zones after Bertrand[34], Caron, *et al.*[22], Ellenberger[11], Nicolas[14], Vialon[9], Wenk[15], and Wunderlich[36], and personal field data in the Ligurian Alps, Briançonnais, the Aosta Valley and Valais. After Lemoine[37] for the External zone. a, Trend of F_1 transverse folds; b, sense of overturning of F_1 folds; c, pre-Senonian folds of the Devoluy; d, pyreneo-Provencal folds; e, northern limit of Pyreneo-Provencal folds; f, overthrust; g, strike–slip fault.

rocks of the eclogite facies; (4) a zone of foliation defined by biotite, sillimanite and anatectic mobilisates, exposed in the Barrovian metamorphic zones of the central Alps[10] where a later high temperature–low pressure metamorphism is super-imposed[4,15] on an earlier high pressure metamorphism.

The style of the phase 1 folds differs depending on which structural zone they occur in.

Briançonnais cover with both internal and external carboniferous basement. No alpine deformation can be found previous to the phase 1 transverse folds. In many areas, the stratigraphic sequence and sedimentary features in the Lutetian flysch noir allow the sense of overturning of the folds to be clearly established (Fig. 1). On all scales, the transverse folds are similar in style and are syn-metamorphic. They are younger than the nummulitic flysch of lower to middle Eocene age. They were formed during the first large scale tangential movements in the Alps, the amplitude of which still remains unknown, under the

overburden of allochtonous Helminthoid flyschs (Upper Cretaceous age) originally emplaced as olistostromes in the Eocene sea.

Savoy sub-Briançonnais zone. The presence of recumbent to isoclinal refolded folds in this zone has been known for long time[16]. The steeply plunging folds which are overturned to the north were formed also during the first penetrative deformation of post-Eocene age.

Piemontese schistes lustrés. The allochthonous character of the schistes lustrés overlying the internal crystalline basement rocks has been proved on the basis of stratigraphic and palaeontological evidence (substitution de couverture)[11] for the massifs of Vanoise, Ambin[11] and Acceglio[17]. The transverse folds have a similar style and trend in both the schistes lustrés and basement rocks[9,11-13,18]. It is postulated that these syn-metamorphic folds are genetically related to the geosynclinal de nappes[11] or the obduction[19] of Piemontese geosynclinal units of Mesozoic age[20] and remnants of oceanic crust[21]. The underlying heterogeneous basement rocks were subsequently rapidly buried under high pressure–low temperature metamorphic conditions, whereas the overburden required for high pressure–low temperature metamorphic conditions in the Piemontese units was represented by Austroalpine units, such as the Dent Blanche Nappe, or by overthrust sheets of ultra-Piemontese flysch.

In the areas where the S_1 cleavage or foliation is horizontal and unaffected by intense secondary penetrative deformation (Gran Paradiso, Dora Maira, Val d'Aoste), the original trend of the transverse folds has been preserved. But in many areas within the zone of the schistes lustrés, the second phase folds are also isoclinal where formed[14,18,22,23] in calcareous schist units and gliding processes related to the secondary deformation have generated a considerable dispersion of the F_1 folds axes. In contrast, the F_2 slip directions show a more regular pattern[23].

The observations made on the very tight first phase folds which affect the meta-banded cherts of Queyras (Cottian Alps) in which the laminated bedding is still preserved, exclude the existence of an earlier penetrative deformation in the Piemontese zone, as recently suggested[22]. F_1 folds in Piemontese rocks have possibly formed as a result of a long period of penetrative deformation (evidently starting in Upper Cretaceous times as suggested by recent dating of HP minerals[24]) during translations of rock units under conditions of constant stress orientation.

In different metamorphic zones where such relations have been established, the high pressure–low temperature minerals are syn to late kinematic[9-14,16,18,22,23,25,27] with respect to transverse folds. The metamorphic zonation is similar to other orogenic belts with alpine-type metamorphism[28]. The width of each of the three principal metamorphic zones[29]: (1) lawsonite $\pm$ jadeite zone; (2) zoisite–glaucophane eclogite zone; (3) kyanite–eclogite zone, is only compatible with sub-horizontal isograds[30], now refolded in detail. Field evidence, for example west of Gran Paradiso, and between Monte Viso and the Briançonnais units, strongly suggests that the isograds plunge westwards and not eastwards, as recently postulated[28].

Fig. 2 North-south longitudinal combined section perpendicular to F_1 folds, showing the possible configuration of the internal crystalline massifs and the Piemontese obduction zone before the arc curvature. The total thickness of units is compatible with high pressure–low temperature or high pressure–high temperature Alpine metamorphism (after ref. 4).
Fig. 3 Possible reconstruction of the western Alps before the arc curvature. The position of the Insubrian plate is the one postulated by Laubscher[7]. Minor rotations of external crystalline massifs are figured. The different structural zones are represented at their actual erosion level. Ophiolites are in black. a, Original trend of F_1 folds; b, direction of tectonic transport.

I would like to put forward a geodynamic model based on this evidence. The radial pattern of transverse folds with respect to the arc is a new factor that has been taken into account in tectogenetic models of the Alps. It seems unlikely that such a pattern could be primary as it would imply a single deformation field of curvature 180°.

In agreement with the data concerning the shortening generated after the F_1 deformation, it seems more likely that the transverse folds were formed when the different structural zones were rectilinear or weakly curved (Figs 2 and 3).

The Dent Blanche Nappe including high pressure granulite facies rocks generally considered to have been formed in the lower crust, belongs to the Insubrian Plate. This plate would have moved initially northwards upon the Piemontese zone, giving rise to high pressure–low temperature metamorphic conditions in the Piemontese units, before its westward later translation. Therefore the basal contact may be regarded as part of a subhorizontal palaeosubduction at the base of the Insubrian sialic crust.

The major thrust, generally interpreted as a retrochevauchement, marking the eastern limit of the Briançonnais zone with external Carboniferous basement, may be regarded as an early major subduction zone, along which the movement revealed by the transverse plunging folds, was essentially horizontal (sinistral wrench fault dipping west). This zone of subduction has been later reactivated and tilted during the F_2 deformation, with a vertical post-metamorphic movement which is particularly spectacular in the Cottian Alps. We recall that the andesitic greywackes of Taveyanne[31] (Priabonian to Lower Oligocene) may be the remnants of a volcanic arc in external position, possibly in connection with westwardly dipping subduction zones. It is not intended here to discuss early kinematics related to downgoing of structural zones and microplates toward the external part of the Alps, which could have acted in the first stages without any penetrative deformation. This subduction was possibly initially related to the expansion of a Tethyan ocean from a Piemontese ridge during Jurassic-Lower Cretaceous times[8].

The constancy of transverse folds in the different structural zones implies horizontal movements and translations of low-angle thrust sheets and small plates of unknown extent towards the NNE, before the arc curvature. At this time (post middle Eocene), the Western Alps must have been a synthetic thrust belt[32]. It is significant that the deformation path compatible with transverse folds is not a contradiction with the motion model in the alpine system at this time deduced from magnetic anomalies in the Atlantic Ocean[33].

The Alpine arc has been generated during the second phase of Alpine deformation, which occurred after a complete change in the relative motion of plates[33]. The arc curvature, formed by the collision of the Insubrian Plate moving westwards (300 km according to Laubscher), reflects the shape of its western edge. The contraction which resulted (Fig. 4), would have been absorbed by three main mechanisms: (1) deep outward under thrusting in the lower crust[35] inducing areas rapidly uplifted and eroded; (2) contraction of each zone by F_2 folding (outward and inward overturned folds are synchronous) mostly responsible for a post-metamorphic flexuration of S_1 cleavage and foliation with sub-vertical Z and for isoclinal folding in the more ductile zones during intense tangential movements. The amount of shortening gradually decreases toward the external zones, where the F_2 folds and cleavage are also younger (post Oligocene) and followed by post Miocene folds, than those of the inner zones (Lower Oligocene); (3) large scale outward translations of the higher units on a continuously rejuvenated and outward moving slope.

This late Alpine phase is characteristic of an antithetic thrust belt[32]. The second phase of Alpine deformation is also responsible for the rapid uplift of high pressure–low

Fig. 4 Transverse schematic section of the western Alps (partly after J. G. Ramsay for the External zone, Ellenberger[11] for the Permo-Carboniferous and Giese[35] for the inferred structure of the Ivrea zone).
temperature metamorphic zones before the establishment of a normal geothermal gradient[7,28] which would have destroyed the metamorphic assemblages as in the central Alps. A considerable part of the global shortening would also have been absorbed by subduction of the schistes lustrés and internal crystalline basements under the Briançonnais zone and external carboniferous basement.

Triassic seaways and the Jurassic Tethys Ocean in the central Mediterranean area

IN the central Mediterranean area phases of middle Triassic and middle Liassic rifting are recognisable. The former produced only relatively deep pelagic basins founded on thinned continental crust; the latter, however, marked the opening of the central Tethys. The Porphyrit-Hornstein and the Diabas-Hornstein formations[1] are the results of such phenomena. During Dogger and Malm times the spreading continued and a large amount of oceanic crust was formed. The Tethys Ocean opened parallel to the long axes of some Triassic deep sea basins and across the long axes of others. Consequently, the positions of Triassic seaways along the southern continental margin of the Tethys 'geosyncline' are defined by the effects of at least two main palaeotectonic events.

In the Triassic System the Germano-Andalusian facies is characterised by prevalent continental deposits, whereas the Alpine facies is characterised by marine deposits. In the circum-Mediterranean area the basements of both Germano-Andalusian and Alpine facies sediments everywhere comprise continental crust which may underlie Palaeozoic sediments and volcanics. Only in the Antalya Nappe (Turkey) are there indications that a crust of oceanic composition underlies the Alpine facies sediments.

The Alpine facies, occurring mainly in the Upper Triassic, is generally represented by shallow water carbonates (dolomites and limestones), and in certain areas by evaporites. Locally,

Halobia limestones are known, showing relatively deep sea environments. The outcrops of *Halobia* limestones form narrow belts, more or less disconnected, which stretch along the circum-Adriatic chains from Greece to Sicily.

The complete Triassic sequence containing the *Halobia* limestones is not much varied in the whole Mediterranean region. The Lower Triassic is represented by shallow water, terrigenous sediments and acid volcanics, which are a prolongation in time of the Upper Permian facies. The Middle Triassic is represented by terrigenous sediments simulating flysch deposits (Monte Facito Formation in the Apennines and Sicily; Montenegro 'flysch' in Yugoslavia), by mafic volcanics (Porphyrit-Hornstein Formation in Yugoslavia and in Greece), and less frequently by nodular limestones like Ammonitico Rossa (Han Bulog Beds in Yugoslavia and in Greece). The Upper Triassic is represented by *Halobia* limestones with interbedded rare mafic lavas and hyaloclastites, and locally by nodular limestones like Ammonitico Rosso (Hallstatt Beds in the eastern Alps).

The *Halobia* limestones have been considered as markers of an oceanic Palaeo-Tethys in the central Mediterranean area[2,3]. I suggest, however, the basins to which pelagic pelecypods and ammonites migrated originated from an eastern oceanic Palaeo-Tethys and penetrated deeply into a continental Palaeo-Mediterranean gulf as 'seaways' founded on thinned continental crust. Among these Triassic seaways the most considerable is the Pindos Basin, which stretches for more than 1,200 km through Greece, Albania and Yugoslavia. On the opposite side of the Adriatic Sea, after a gap of some 100 km, the basin is recognisable in the southern Apennines–Sicily arc as unconnected outcrops stretching for about 800 km.

In Jurassic times a real ocean separated the European and the African continents. Contemporaneously, large shearing movements began between Europe and Africa as a result of the opening of the southern Atlantic[4].

Jurassic Tethyan deposits consist of mafic and ultramafic rocks, radiolarites, pelagic limestones, claystones and sandstones, frequently affected by high pressure–low temperature metamorphism.

A basic assumption in any attempt at a palinspastic restoration of Triassic and Jurassic palaeogeography[3,5] is that the volume of continental crust remained roughly the same before and after the Alpine deformation. Consequently, the kinematic system is considered a closed system. But a lot of continental crust must have disappeared into the asthenosphere[6,7] and, therefore, huge volumes (or surfaces in a two-dimensional

Fig. 1 Palinspastic restoration of Upper Triassic palaeogeography in the central Mediterranean area. *a*, Stable areas with slight subsidence; *b*, subsided basins of Germano-Andalusian facies; *c*, shallow-water carbonates of Alpine facies; *d*, 'seaways'; 1, Sicani zone; 2, Imerese zone; 3, Lagonegro zone; 4, Triassic pelagic sediments of Slovenia; 5, Budva-Kotor zone; 6, Pindos zone; 7, Australpine of Hallstatt; 8, Australpine of the Gemerides; 9, Australpine of the Balaton Lake; 10, Subpelagonian Triassic pelagic limestones of Serbia; 11, Subpelagonian Triassic pelagic limestones of Northern Pindos and Othrys.
Fig. 2   The Tethys Ocean in the central Mediterranean area.

calculation) have been taken out of the system. These lost volumes are not counterbalanced by additional small volumes of new oceanic crust. In any palinspastic restoration it is therefore necessary to smooth out all the nappes of the peri-Mediterranean Alpine systems to calculate the real shortening of the plate margins during the Alpine compression. Figures 1 and 2 attempt such a palinspastic restoration for the Upper Triassic and Upper Jurassic. The original position of the palaeogeographical units has been obtained by fixing the 'stable' European and the Saharan plates, smoothing out folds and nappes, removing the main lateral displacements and connecting those belts which are common to the African and European margins. This construction of the Western part of Fig. 2 relied upon the palinspastic restoration of Laubscher[7].

This reconstruction produces an area corresponding to the Alpine facies, forming a gulf open in the direction of the Palaeo-Tethys and surrounded by regions characterised by Germano–Andalusian facies. In these regions it is possible to distinguish stable zones, slightly subsident and unaffected by synsedimentary tectonics, and less stable or clearly unstable zones, characterised by high rates of subsidence and sedimentation, synsedimentary faulting and mafic volcanism.

In the area comprising Alpine facies the palaeogeography changes radically from the Lower to the Upper Triassic because of a Middle Triassic tectonic phase, which was responsible for the tectonic regime immediately before the opening of the Tethys. This tectonic phase included an attempt at rifting, which produced a complex system of tensional faults that crossed the Palaeo-Mediterranean Gulf in several directions. The faulted blocks underwent different vertical movements. The uplifted blocks often underwent severe erosion, whereas flysch-like sediments were deposited on the downshifted blocks. Contemporaneously, widespread mafic magmatic activity (comprising an alkali-basaltic series) occurred along the main faults. Deep sea basins developed along preferential directions (probably corresponding to strips of crustal thinning) within the Palaeo-Mediterranean Gulf, allowing the diffusion of the pelagic fauna from the Triassic Palaeo-Tethys through Turkey, Greece, Albania, Yugoslavia, Hungary, Czechoslovakia, Austria, Italy, and as far as western Sicily. The absolute homogeneity of the fauna proves that close intercommunications were established between all of the seaways. Figure 1 shows the region during the late Triassic.

During Liassic times, starting mainly in the Middle Liassic, important new events occurred in the central Mediterranean area: along giant tensional fractures, partly parallel to, and partly discordant with, the former seaways, the Tethys Ocean began to open. In the internal nappes of the Dinarides and of the Hellenides at least two main ophiolite assemblages deriving from the oceanic Tethys may be distinguished: the Diabas-Hornstein Formation, and the ultrabasic massifs at Zlatibor and Vourinos, with their basalts and sediments. The

Diabas-Hornstein Formation comprises alternated diabases, radiolarian cherts, sandstones, claystones, graded calcareous microbreccias, allodapic and pelagic limestones, and intraformational conglomerates. This sequence may overlie Jurassic limestones founded on continental crust[8].

The generally tectonic basal contact and the occurrence of slices of serpentinites between the Jurassic limestones and the Diabas-Hornstein Formation suggest that the latter (at least in part) was possibly founded on oceanic crust. On the other hand, the occurrence of terrigenous material and of neritic calcareous turbidites suggests provenance on a very near continental platform. I suggest that the Diabas-Hornstein Formation is the product of the Liassic rifting which marked the beginning of the opening of the Tethys Ocean, so it may be considered as a marker of the continental margin or the continental rise. As the opening of the Tethys Ocean continued, the areas in which the Diabas-Hornstein Formation had been deposited were shifted laterally and, according to plate accretion models, new areas of oceanic crust were generated in their place. These new areas of oceanic ridges which are, of course, younger than the Diabas-Hornstein Formation, are today recognisable as the ultramafic massifs.

In the Alps and in the Apennines this distinction between initial rifting (Diabas-Hornstein Formation) and real ocean spreading (ultramafic massifs) of the central Tethys is not so clear as it is in the Dinarides, but it is probable that the Ligurian and Piemontese ultramafic rocks represent an ancient, oceanic ridge area, whereas parts of the Southpennine *Bundnerschiefer* represent an equivalent of the Diabas-Hornstein Formation.

During the Middle and Upper Liassic the combination between the Atlantic and the Tethyan movements produced a renewal of synsedimentary tectonic activity, and consequently the palaeogeography became modified not only around the central Tethys, but also around the former Triassic seaways. For example, in western Sicily the former Imerese seaway, which during the Upper Triassic ended at the longitude of Palermo, suddenly lengthened westwards during the Liassic, in the direction of the Maghreb along a newly generated deep furrow in which radiolarian oozes and calcareous turbidites stratigraphically overlie collapsed shallow water dolomites[9]. Contemporaneously, in areas of maximal tension (Imerese, Sicani, Pindos), flows of alkali-basalts were erupted.

During post-Jurassic times the Triassic seaways near to the margin of the Tethys Ocean, and those which were cut across by the opening of the ocean, were affected by Cretaceous compression. These orogenic phases, the earliest in the central Mediterranean area, were responsible for the reduction, and the local disappearance, of large oceanic zones. In Greece (Northern Pindos[10] and Othrys), sediments deposited very near to the Tethys Ocean–Triassic seaways were affected by Cretaceous compression, and were involved in the building of the ophiolite nappes.

On the other hand, the continuing sedimentary history of those seaways which lie more within continental areas, will cease only after the collision between Europe and Africa. In Sicily (Sicani Mountains[11]), such sedimentary deposits were affected by compression during the Upper Miocene, when Europe and Africa had already collided and a lot of continental crust from both plates had disappeared because of subduction.

Laser microprobe mass analysis of organic materials

LASER microprobes currently in use combine a laser microscope with a light emission spectrometer[1-3]. Recent improvements in instrumentation have demonstrated the limitations of this method with respect to spatial resolution (some μm) and detection capability (10^{-13}–10^{-15} g). Much lower detection limits (10^{-18} g) have been obtained in ultrathin sections with electron probe X-ray microanalysers[4,5], although the latter, however, do not satisfy many needs of biologists. Neither trace
Fig. 1 Schematic diagram of laser microprobe mass analyser.

element detection in the parts per 10^9 range nor analytical information about organic constituents car be obtained. In the case of the main physiological electrolytes, biologists are primarily interested in the cellular and subcellular transport

kinetics of Na^+, K^+, Mg^{2+}, and Ca^{2+}, indicating a need for microprobe techniques capable of analysing isotopes. A mass spectrometer in combination with a laser microprobe seems to be a very attractive approach. In principle, it should enable not only high sensitivity but also isotope analysis and the 'fingerprinting' of organic molecules, provided they do not decompose into fragments too small for recognition of the parent molecules. The special requirements for biomedical application are satisfied by the laser microprobe mass analyser (LAMMA) described here.

The instrument (Fig. 1) combines a time-of-flight mass spectrometer with a laser optical device. The latter consists of an incident light microscope and a Q-switched, frequency-doubled ruby laser ($\lambda = 347$ nm). The specimen is mounted on a form-var-coated electron-microscope grid fixed to the lower side of a microscopic cover glass with no further support underneath (Fig. 1). In addition the cover glass serves as the vacuum window of the time-of-flight mass spectrometer. This arrangement enables free expansion of the laser-generated microplasma into the mass spectrometer. Maximum optical resolution is obtained using an immersion objective. Sampling areas (down to 0.5 μm in diameter and almost limited by diffraction) could be achieved reproducibly in a rather broad variety of unstained biological materials by adjusting the laser power density in the focus between 5×10^8 and 5×10^9 W cm^{-2} (ref. 6).

The time-of-flight spectrometer consists of a 3 kV acceleration grid, 4 mm below the sample plane, an einzel lens, a field-free drift tube of approximately 1 m in length and an electron multiplier as ion detector. The overall transmission of the mass spectrometer depends on the directional distribution of the initial ion velocity. Rough calculations indicated that a transmission of 1 % or better could be achieved if the initial energy of the ions remained below 50 eV. Measurements showed that, in the conditions chosen, ions had mean initial energies of 5–30 eV (ref. 6). Accordingly the calculated peak half width at mass number 39 is less than 0.15 a.m.u. which means that, theoretically, a resolution of $m/\Delta m = 260$ should be possible. The experimental peak half-width is, however, limited by the recording electronics, which consisted of an impedance matching preamplifier, a fast transient recorder and a strip chart or magnetic tape recorder. To determine sensitivity and resolution of the microanalyser as well as the reproducibility of recorded spectra, standard specimens were prepared according to a suggestion made by Spurr[7]. Organometallic complexes formed from macrocyclic polyethers and inorganic ions such as Li^+, Na^+, Mg^{2+}, K^+, Ca^{2+} and Co^{2+} were dissolved in epoxy resin to give final doping concentrations in the range 10^{-2}–10^{-6} weight fraction. Sections (0.1–1.0 μm thick) were cut on a microtome.

Figure 2 shows two mass spectra obtained from such epoxy standards doped with Li, Mg, and Co. In spectrum (a) the expected signals of Li, Mg, and Co can be readily identified as well as those from Na and K contained in the epoxy resin as impurities. Most of the other peaks seem to represent fragments of the organic matrix. In spectrum (b) many of these signals exceed the dynamic range of the transient recorder, which was set to obtain optimum recording of the
Fig. 2 Mass spectra obtained from epoxy resin, doped with L, Mg, and Co. a, Sample doped with 4×10^{-5} weight fraction (40 p p m.) of each of the inorganic ions. b, Sample with a doping of only 5×10^{-6} (5 p.p.m). b was recorded at an instrument sensitivity ten times that of a. In both cases the sampled volume was 3.5×10^{-13} cm^3 corresponding to a mass of 3.9×10^{-13} g (diameter 1.5 μm, thickness 0.2 μm). The electronically added laser signal serves as zero time mark of the time-of-flight scale and as laser output control.

Li isotopes. The relative peak heights of [6]Li and [7]Li correspond quite reproducibly with the natural abundances of 7.5% [6]Li and 92.5% [7]Li. For Mg this correspondence is lost in the statistical fluctuations of the rather small signals at mass numbers 24 (natural abundance 79%), 25 (10%) and 26 (11%). A partial masking of the Mg signals by mass interfering molecules may be one of the reasons for this.

The overall sensitivity of the instrument is estimated from spectrum (b). With a probed mass of 3.9×10^{-13} g and [6]Li present at a weight fraction of 4×10^{-7} (0.4 p.p.m.), 1.4×10^{-19} g or 1.4×10^{-4} atoms [6]Li were detected. This sensitivity is at least one order of magnitude better than that achieved in electron probe X-ray microanalysis. Further improvements are possible as in this experiment neither the multiplier nor the preamplifier were optimised.

Peak half-widths so far obtained are less than 0.3 a.m.u. at mass number 39 (K). This is, of course, more than is needed to resolve natural isotopes. In mass ranges in which large amounts of organic fragments occur, however, it may be difficult to separate small peaks of trace elements from those of components with nominally the same mass number, for example, Si may be obscured by C_2H_4 or CO. On the other hand, preliminary spectra from freeze-dried specimens of kidney, frog skin, or human erythrocytes have shown Na and K peaks much in excess of those of the organic fragments, the ion yield of which is obviously comparatively small.

In spite of the positive features of the method with respect to sensitivity and resolving power, quantitative analysis still poses some problems. Both ion yield and transmission depend on the ion species under investigation. Moreover the laser radiation–solid interaction involves some highly non-linear processes which make reproducibility from shot to shot rather poor. The best results so far achieved with standard specimens exhibit a s.d. of ±20% in the case of [7]Li. The signals of other elements vary by more than an order of magnitude (C peaks, Fig. 2). This is approximately twice the s.d. found in electron probe X-ray microanalysis of similar specimens[8]. It is expected that systematic optimisation of the laser operating conditions will overcome this problem.

Stability of complex ecosystems

ECOLOGISTS have generally held that a complex ecosystem is more likely to be stable than is a simpler one. Gardner and Ashby[1] have shown, however, that for randomly connected linear systems the probability that the equilibrium will be stable actually decreases as the complexity increases. Of course, whether or not this is a contradiction depends very much on what is meant by stability. It is doubtful that field ecologists are really thinking of the relative likelihoods that systems of

different types will persist; it is, after all, only those systems which persist which are observed and about which generalisations are made. The reason for connecting stability and complexity seems rather to have been the observation that large scale population oscillations are much more common in simple ecosystems than in complex ones[2,3]. We have therefore considered the following problem: Given that a system is near a stable steady state, will increased complexity tend to increase or to decrease the rate at which perturbations die out?

We have constructed random matrices according to the procedure suggested by Daniels and Mackay[4]: the diagonal elements a_{ii} ($i=1, 2, \ldots, N$) were taken from the uniform distribution on $(-1, -0.1)$ and a specified fraction C of the off-diagonal elements were taken from the uniform distribution on $(-1, 1)$. The remaining elements were set equal to zero. We found the eigenvalues λ_j, discarded all those matrices which were not stable, and for the stable matrices computed the value of

$$D = \frac{1}{N} \sum_{j=1}^{N} \exp\{\mathrm{Re}(\lambda_j)\}$$

This represents the magnitude after one unit of time of a unit perturbation which was originally distributed equally in all the eigendirections, and is thus a measure of the mean damping in the associated linear system. We also computed D averaging over all matrices, stable or not, but, as we expected, D then increased with both N and C: for $N=8$ and $C=0.6$, for example, D was 0.721.

The observed lack of dependence of D on complexity may be surprising, but there is evidence to show that it is not artefactual. For example, the similar expression $\exp(\Sigma \mathrm{Re}(\lambda_j)/N)$, which is formed from the trace of the stability matrix, is totally independent of both N and C, and although it is not in general equal to D, the difference is much smaller when all the $\mathrm{Re}(\lambda_j)$ are negative, as the effect of exponentiation is less. Consider also the two-species linear system, the eigenvalues for which are

$$\lambda = \tfrac{1}{2}[a_{11}+a_{22} \pm ((a_{11}-a_{22})^2 - 4a_{12}a_{21})^{1/2}]$$

If the eigenvalues are complex, that is, if there are any oscillations at all, then the rate of damping is entirely independent of the interaction terms a_{12} and a_{21}. If, on the other hand, the eigenvalues are real, then if the system is to be stable the eigenvalues are restricted to the range $(a_{11}+a_{22}, 0)$. If a_{12} and a_{21} are larger than a_{11} and a_{22}, then the effect will not be to increase (or decrease) the damping, but either to produce oscillations or destabilise the system, depending on the sign of $a_{12}a_{21}$. These features are consistent with those found numerically in larger systems.

We conclude that whereas increasing N or C decreases the probability that a randomly connected linear system will be stable, once it is given that such a system is stable, the rate at which perturbations die out does not depend on the complexity. Damping seems to be caused mainly by the self-limitation terms, whereas the chief effect of interactions between species is to produce oscillations.

How can we reconcile these results with the existence in nature of complex ecosystems which are stable and in which there do not seem to be population oscillations on the same scale found in simpler systems? May[5] has argued that we need not be unduly concerned about the prediction that complex systems are likely to be unstable, because what we observe is not a random sample of arbitrary systems but rather only those which have evolved in such a way as to produce stability and therefore persistence. But this line of reasoning does not explain the lack of oscillations in complex systems. We believe that the solution to both problems may lie in a difficulty in the definition of complexity first pointed out by Somoraji and Goswami[6]. The stability matrix is a matrix of first derivatives, and C' (which ought properly to be called the linear connectivity) thus measures not the total number of inter-

Table 1   Persistence of oscillations as a function of complexity

Mean (μ) and s.d. (σ) of D for values of N and C chosen to cover the range for which the probability of stability is non-negligible. Number of stable matrices (n) out of 500 in each case is also shown When $C=0$ then $\mu=0 597$ for any N.

actions between species, but only those such that at equilibrium a small change in the population density of one species produces a direct change in the net specific growth rate of another. There seems no reason to suppose that the majority of interactions within an ecosystem fall into this class; it excludes, for example, the obviously vital connection between a predator and its only prey, in any situation in which the prey is in excess and the predator is limited by some other factor, such as space. If large, complex systems have the property that their linear connectivity is low, then they are more likely to be stable, and if stable, are more likely to be over-damped than to oscillate. An example of this behaviour can be found in the analysis of an n-species food chain[7]. And only ecosystems with relatively few species can have a sufficiently high linear connectivity to produce oscillations without becoming unstable— which would explain why it is that population oscillations are observed in the arctic but not in the tropics.

Plant growth substances and effects of photoperiod on flower bud development in *Phaseolus vulgaris*

THE flower buds of certain varieties of *Phaseolus vulgaris* absciss in British summers, a phenomenon which is induced when the plants are grown in day lengths longer than 13–14 h[1]. The number of buds which absciss increases as the day length is extended[1-3]. This post-initiation effect is truly photoperiodic, the photoperiodic stimulus being received in the leaves and the inhibitory effects expressed in the buds, the growth of which is inhibited before they finally drop[2-3]. Experiments in which a single trifoliate leaf was exposed to a photoperiod different from the rest of the plant provided indirect evidence that the effects of photoperiod on flower bud development were mediated through the production of substances in the leaves, with a predominance of inhibitor(s) being formed in long days and of promoter(s) in short days[3,4]. We describe here the determination in a single sensitive variety, classified as P47, of the chemical basis for

the inhibitory and promotory effects of long and short days respectively.

Exogenous application of either indolylacetic acid or gibberellic acid to the leaves or flower buds of plants kept in short days failed to induce the bud abscission experienced in long days[3,4]. In contrast, however, it has now been found[6] that application of synthetic abscisic acid (ABA) to the differentiating flower buds of plants in short days results in inhibition and finally abscission of many of the buds at a later stage of development. For example, when ABA was applied in a droplet of solution daily for 7 d (range 0 1–5 4 μg per application), the extent of flower bud abscission over the whole plant depended on the amount of ABA applied, the effect being most marked on those buds carried on the terminal inflorescence and at the uppermost node. Endogenous ABA extracted from plants grown in long days and re-applied to plants in short days evoked effects similar to those of the synthetic compound. On the other hand, exogenous application of the chemically related inhibitor, xanthoxin, did not induce flower bud abscission.

In view of the above results, indicating the possible participation of ABA in the regulation of flower bud development in this variety, numerous experiments were carried out during the summers of 1970–72 to study the effects of photoperiod on the endogenous concentrations of ABA ABA, both free and bound, was extracted[7] from different organs and the concentrations estimated, mostly by wheat coleoptile bioassay[8], with some confirmed by gas liquid chromatography[9]. The two methods gave results of the same order whether the tissues contained low or relatively high concentrations of ABA; for example, two different samples of leaves gave results by bioassay and gas liquid chromatography, respectively, of 33.5 and 35.4 μg per kg fresh tissue, and 225 and 208 μg per kg fresh tissue, these figures all being averages of several complete analyses of each extract.

Our experiments showed that the leaves and buds of plants grown in long days contained more ABA than those in short days (Table 1). The concentrations of ABA in the leaves, buds, petioles and stems of plants grown in an 18 h photoperiod (in which the buds were severely inhibited) were higher than those in the corresponding organs of plants grown in an 8 h photoperiod (in which bud development was normal). These differences in ABA concentrations were large in the youngest leaves but smaller in the mature leaves. The highest concentrations of ABA were found in the inhibited buds; these buds also contained considerable amounts of bound ABA.

Table 1   Concentration of ABA (μg per kg fresh tissue) in *Phaseolus vulgaris*, var. P47, grown in different photoperiods

Organ	Photoperiod 8 h	18 h
First trifoliate leaves	42	51
Second trifoliate leaves	21	37
Third trifoliate leaves	39	55
Fourth trifoliate leaves	30	91
Fifth trifoliate leaves (unfolding)	20	305
Combined petioles	11	36
Stems	18	29
Terminal flower buds	121 (9)*	729 (60)*

* Bound ABA in parentheses

Seeds were sown on May 5, 1972. In any 24 h periods all plants received 8 h natural daylight in a greenhouse, followed by either 0 or 10 h incandescent light (540 lx at pot level) in two photoperiod rooms, each maintained at 20 $\pm$ 1 °C. Plants were collected on June 7 when the final trifoliate leaf was unfolding and the flower buds on the plants in the 8 h photoperiod were just about to open. The individual organs from the plants were combined and extracted, and determinations were carried out by wheat coleoptile bioassay.
Fig. 1 Effect of cytokinins on the cumulative number of open flowers in long days. Plants were grown in a greenhouse for 8 h, extended to 16 h by incandescent light in a photoperiod room. From 15 d after sowing 10 μl solution containing 0.1 μg kinetin or 6-benzyl-aminopurine were added to the stem apex daily for 10 d. Data are totals of five plants. O, Kinetin; □, 6-benzyl-aminopurine. Control values remained at zero.

The above results, together with the effects of exogenously applied ABA, provide strong evidence that ABA plays an important role in mediating the effects of long days on flower bud development in variety P47. It would seem that under the influence of long photoperiods there is a greater production of ABA in the leaves and an increased accumulation of the substance in the buds, leading eventually to their inhibition and abscission. This was substantiated by a single experiment in which the abscissing buds were found to contain more free and bound ABA (331 and 70 μg per 100 g dry weight) than they did 6 d previously (105 and 0 μg per 100 g dry weight, respectively).

Evidence that promotory as well as inhibitory substances are involved in mediating the effects of photoperiod was obtained when cytokinins were applied to bean plants grown in long days[10]. Here it was found that kinetin or 6-benzyl-aminopurine stimulated the development of flower buds which would otherwise have dropped (Fig. 1) No study has yet been made on the endogenous concentrations of cytokinins in the bean variety P47; note, however, that the concentrations of cytokinins in both the leaves of *Begonia*[11] and the xylem sap of *Perilla*[12] were found to be higher in short days than in long days.

Previous work on the inhibitory and promotory effects of photoperiod on flowering in various species has concentrated on the process of floral initiation or more generally on flowering, and the identification of the plant growth substances involved has proved difficult[13]. The present study is therefore of particular significance in referring specifically to the effects of photoperiod on flower bud development after the initiation of the floral primordia, and provides evidence as to the identity of the inhibitory and promotory substances involved.

Suppression of apparent movement during binocular rivalry

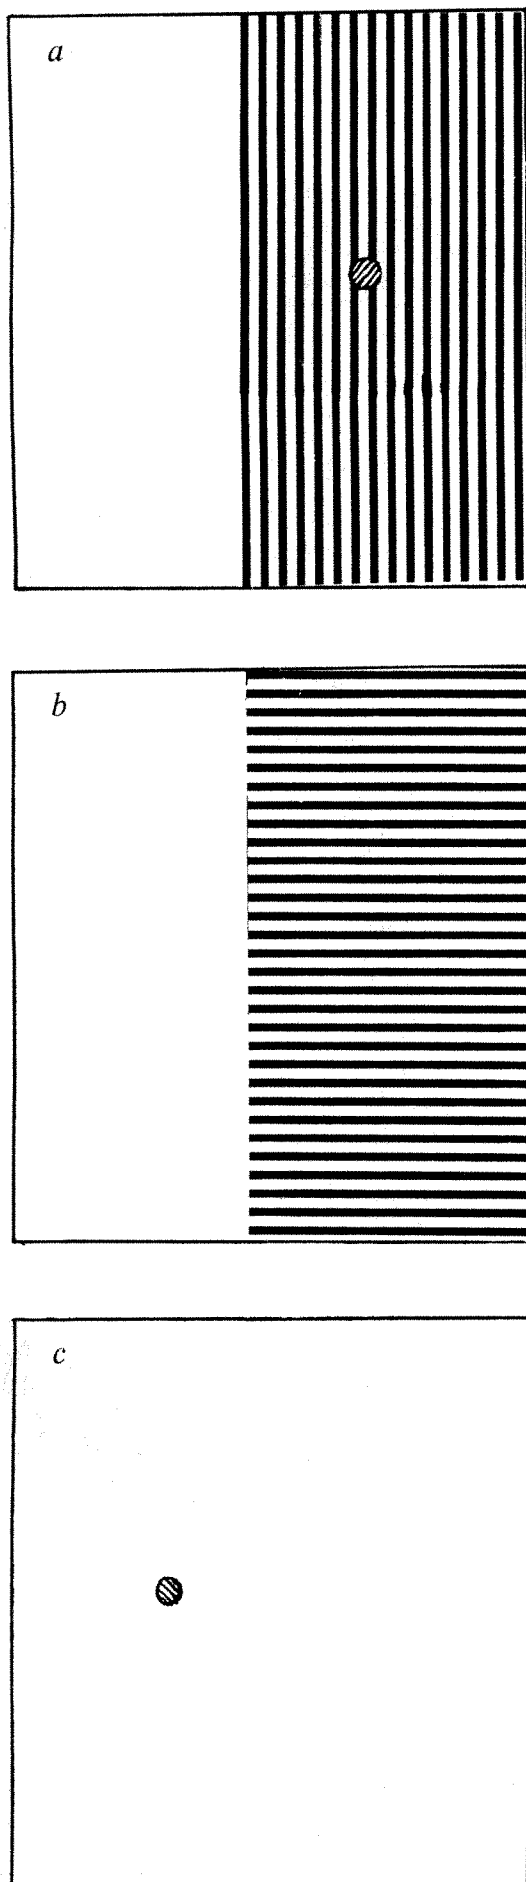
STEREOSCOPIC depth perception can coexist with binocular rivalry of form and colour[1-3]. If a stereogram is viewed with a red filter in front of one eye and a green filter in front of the other eye (or with an oblique grating superimposed on one eye's picture and an orthogonal grating on the other picture), then stereopsis can still be obtained in spite of the two eyes' pictures being seen alternately rather than simultaneously. Although one image is 'suppressed' in consciousness, information about its position is preserved and used for stereopsis. This finding implies either that stereoscopic depth perception 'precedes' the site of binocular rivalry in the visual system or that conscious perception and stereopsis are independent visual functions mediated in 'parallel' neural channels. Here I consider the related question of whether an image that is suppressed during binocular rivalry (and is, therefore, not 'seen' by the observer) can contribute to the perception of apparent movement.

The display used in the experiment is illustrated in Fig. 1. Figure 1a and b were presented to the right and left eyes, respectively, in a three-channel tachistoscope driven by an electronic timer They subtended 9° and were of equal average luminance. Crossed polaroids were used to separate the two eyes' pictures The stimuli were high contrast horizontal (Fig 1b) and vertical (Fig 1a) gratings presented to one half-field alone in each eye. Figure 1a contained, in addition, a bright round yellow spot fixed to the centre of the grating. Figure 1c was displayed on the third channel either to the left eye alone (in one experimental condition) or to both eyes (in another condition), and contained only a yellow spot.

Four experienced observers were used in the experiment. They were instructed to press a button which illuminated Fig. 1a and b simultaneously These would stay on as long as the button was held pressed. When the button was released a and b would go off simultaneously and c would appear in the other half-field after a brief delay of 75 ms.

Initially b was excluded from the circuit and the observers familiarised themselves with apparent movement of the yellow spot between a and c by alternately pressing and releasing the button (the distance between these spots was about 3.5°). b was then included in the cycle. When the observers now pressed the button they could see rivalry between the striped half-fields in a and b. Sometimes periods of complete suppression would be observed and no yellow spot would be seen when the horizontal grating in the left eye b was suppressing the vertical grating in the right eye a. The observers were instructed to release the button during such periods of complete suppression of a and to observe whether the yellow spot in c seemed just to appear from nowhere or whether it seemed to move to its present location from its original (imaginary) location in a. They were encouraged to repeat the procedure as often as they liked before making a decision Specifically, they were asked to compare the effect of releasing the button during suppression of a, when the yellow spot was not visible, with the effect of releasing it during suppression of b.

All four observers reported that no apparent movement

Fig. 1 *a*, Right; *b*, left; *c*, left or both.


could be seen if the button was released when the yellow spot was being suppressed, suggesting that retinal rivalry precedes movement perception in the visual system. This was true irrespective of whether *c* was presented to the left eye alone or to both eyes. One of them, however, noted that if the button was released immediately following suppression then some vague impression of movement could, in fact, be obtained, presumably because the suppression itself took the place of switching off the light spot. If there was any delay between suppression and button release, then, like the other three observers, he saw no movement but only a single light spot *c* blinking on and off.

In this context it may be useful to think of apparent movement as an 'unconscious inference'[5-7] that a visible object has changed its location rather than as an expression of the time constants of hypothetical 'motion detectors'. The brain may judge it improbable that the disappearance of a stimulus should be followed so soon by the sudden and independent appearance of an identical stimulus nearby and may therefore decide that the original stimulus must in fact have moved to this new location. As conscious perception may be a necessary prerequisite for any cognitive inferential process of this nature it is perhaps not surprising that a suppressed and invisible image cannot contribute to apparent movement perception.

This view is not necessarily inconsistent with the ideas of Anstis[8], Julesz[9] and Braddick[10], as apparent movement is probably not a unitary process. The effects observed by these investigators using Julesz patterns may well be the result of activation of motion detectors at a relatively peripheral level in the nervous system. In fact Julesz[9] and Kolers[4] have argued before that motion perception may involve many different levels of processing.

The suppression of apparent movement during rivalry raises the related question of whether a single image can simultaneously contribute to stereopsis and apparent movement perception. To answer this question, the two half-images of a wheatstone stereogram were presented briefly to each eye alternately rather than simultaneously. (The interstimulus interval was 100 ms, and each stimulus lasted 100 ms.) If the disparity was large (1–2°) then the observers reported simultaneous stereo-depth and interocular horizontal apparent movement. This observation suggests that movement and depth perception are probably mediated in parallel neural channels with overlapping time constants.

I thank Dr O. Braddick and Alan Adlard for help and suggestions.

Immunobiology of membrane-bound collagen on mouse fibroblasts

THERE is ample evidence that collagen is produced by fibroblasts[1-5]. Following biosynthesis in ribosomes, collagen is thought to be transported to the periphery by microtubules[6] but very little is known about the biology of collagen in cell membranes. We report that collagen is membrane-bound, that it is patched and capped by anti-collagen sera, and that the
Fig. 1 Membrane immunofluorescence of mouse L-cell fibroblasts with rabbit anti-collagen serum. Reaction at 4° C (*a*), 22° C (*b*) and 37° C (*c*). Cells (1 × 10⁶) in 1 ml Eagle's MEM containing 3% FCS and HEPES buffer at specified temperatures were reacted with 30 μl of rabbit anti-rat skin collagen sera for 20 min, washed twice in medium, stained with fluorescein isothiocyanate (FITC) sheep anti-rabbit Ig (Wellcome, UK) for 20 min, washed three times in medium, suspended in 40% glycerol, and examined for membrane immunofluorescence in a Zeiss photomicroscope 2 equipped for epi-illumination[17]. Anti-collagen specificity was indicated for the antiserum according to the following major criteria: (1) by showing that the amino acid content of the antigen was consistent with collagen, and that the antigen contained no anti-rat or anti-mouse serum proteins using immunoelectrophoresis and Ouchterlony analysis; (2) by showing that the antiserum stained rat and mouse tissues in a collagen distribution using immunofluorescence according to Rothbard and Watson[16]; that the antiserum agglutinated collagen-coated sheep erythrocytes treated with tannic acid and that the staining of tissues and fibroblasts as well as the agglutination of red cells was removed by chromatography of the antiserum on rat collagen-coated beads of CnBr-activated sepharose or Degalan beads (Degussa, Frankfurt); (3) by showing that the antiserum did not precipitate rat or mouse serum proteins by immunoelectrophoresis or Ouchterlony analysis, and that it did not stain the cell membranes of mouse leukocytes or erythrocytes; (4) by showing that the antibody stained fibres in mouse tissues with collagen periodicity in the electron microscope using the antibody-peroxidase technique[25].

mobility of membrane-bound collagen is influenced by temperature and vinca alkaloids. The identification of membrane-bound collagen as a fibroblast marker would augment existing definitions of these cells, and would perhaps allow the application of certain immunological techniques to study collagen secretion by manipulating membrane-bound collagen with antibodies, lymphocytes, and so on.

Several proteins and receptors on fibroblasts have been studied immunologically. Histocompatibility antigens of mouse fibroblasts patch and cap with anti-H2 sera[7,8]; concanavalin A (con A) receptors on mouse 3T3 cells patch when treated with con A-ferritin complexes and anti-ferritin[9]; phytohaemagglutinin (PHA) receptors have been demonstrated on mouse L cells by agglutination and immunofluorescence techniques (A.T. and W.P.F., unpublished); and several types of mouse fibroblasts form spontaneous rosettes with erythrocytes[10,11]. The redistribution of these membrane structures are generally inhibited by low temperature or certain chemicals, usually vinca alkaloids. Although these reactions are specific, they are not unique to fibroblasts.

We used mouse (H2ᵏ) L-cell fibroblasts grown in Eagle's MEM supplemented with L-glutamine, 10% foetal calf serum (FCS) and 20 μg ml⁻¹ ascorbic acid. These cells were judged morphologically to be fibroblasts, and fixed cells were indirectly stained for collagen with anti-collagen serum[12]. The fibroblasts were grown to confluence in Falcon 3025 tissue culture flasks (75 cm²) and removed using either 0.2% trypsin for 10 min or 1% EDTA in phosphate buffered saline (PBS). After washing, the cells were suspended at a concentration of 1 × 10⁶ per ml in Eagle's MEM containing HEPES buffer and 3% FCS. Their

viability was greater than 99% as demonstrated by the exclusion of 0.1% trypan blue and by the intracellular hydrolysis of fluorescein diacetate[13]. These cells were then studied for membrane immunofluorescence using rabbit antisera to acid-soluble rat skin collagen. The antisera were prepared by first extracting an acid-soluble collagen antigen from rat skins with acetic acid according to the method of Bornstein and Piez[14]. The rat skin collagen, precipitated seven times, contained no rat serum proteins as demonstrated by immunoelectrophoresis against a potent, precipitating sheep antiserum to rat serum proteins, and the amino acid content of this antigen was consistent with collagen. Antisera were raised in rabbits immunised with 2 mg collagen in 1.5 ml Freund's adjuvant containing heat-killed *Mycobacterium tuberculosis*, followed 1 month later by 2 mg alum-precipitated[15] collagen intraperitoneally. A 1:100,000 dilution of the antisera agglutinated collagen-coated tanned sheep red blood cells, and this was inhibited by the addition of native rat or mouse skin collagens but not by native human skin collagen. The antisera did not precipitate rat or mouse serum proteins by immunoelectrophoresis. The sera produced a collagen pattern of staining[16] on cryostat sections of rat and mouse tissues but not on human tissues. The immunofluorescence in all of these experiments was carried out according to Faulk and Hijmans[17] (see Figs 1 and 2).

Viable L-cell fibroblasts produced a patchy, occasionally capped, pattern of membrane spots when stained at 22 °C with rabbit antisera to rat skin collagen (Fig. 1*b*). When this was performed at 4 °C the pattern of staining was homogeneous (Fig. 1*a*), and capped cells were seen when it was carried out at 37 °C (Fig. 1*c*). The transition from 4 °C to 37 °C (that is, transition of staining patterns from homogeneous to patch to cap) involved the coalescence of discrete membrane spots into a cap (Fig. 2). This transition did not occur in the presence of either colchicine or vinblastin, but was observed in the presence of cytochalasin B (Table 1). Cells treated at 37 °C with colchicine or vinblastin did not cap but had a characteristic pattern of peripheral staining. We were unable to observe a

Fig. 2 Coalescence of membrane-bound patches into a cap of collagen staining. L-cell fibroblasts treated with rabbit anti-collagen sera and FITC sheep anti-rabbit Ig. Control reagents for this experiment included (a) normal rabbit serum, normal human serum and normal sheep serum; (b) sheep anti-human normal serum and sheep anti-con A, and (c) FITC sheep anti-swine Ig and FITC rabbit anti-human Ig. All of these were negative. Arrows indicate the general direction of movement for patches of membrane-bound collagen to form a cap. We anticipate that, under suitable conditions, this is followed by secretion of collagen[11].
Table 1 Effect of temperature, cytochalasin B and vinca alkaloids on fibroblast patch and cap reactions with anti-collagen sera

Temperature	Reagent	Amount of reagent	Patch (%)	Cap (%)
4° C	PBS	—	5	none
37° C	PBS	—	>95	35
37° C	Cytochalasin	10 µg ml^{-1}	>95	37
37° C	Colchicine	10^{-5} M	>95	<5
37° C	Vinblastin	10^{-5} M	>95	<5

Cytochalasin B (Aldrich, UK), colchicine and vinblastin (Sigma, UK) were used. The cytochalasin B was dissolved in dimethyl sulphoxide at a concentration of 10 mg ml^{-1}. DMSO control had no observable effect on membrane immunofluorescence.

difference in collagen staining between cells collected using trypsin and EDTA.

Incubation of trypsin harvested cells for 1 h with 50 units of collagenase (BDH) under optimal conditions for the enzyme[1] still gave the usual staining pattern with anti-collagen sera. Subsequent incubation of collagenase-treated cells with 500 units of pronase (Koch-Light, *S. griseus*) for 1 h at 37 °C became negative for collegen staining. Pronase alone, however, was found to be responsible for this result. Pronase-treated cells giving no reaction for membrane-bound collagen become positive after 3 h incubation in complete medium containing ascorbic acid. The failure of collagenase to remove membrane-bound collagen is consistent with the observation that rabbit anti-collagen serum is primarily directed to terminal (telopeptide) antigenic sites, and not to helical or central sites[18].

Membrane-bound collagen may be unique to fibroblasts in a manner analogous to membrane-bound Ig being unique to B lymphocytes. This is not to imply that other cells cannot make collagen[19]. The membrane-bound collagen is mobile and temperature sensitive; its membrane mobility is partially inhibited by vinca alkaloids, suggesting a role for microtubules[20] in the mobility of membrane-bound collagen. The presence of membrane-bound collagen seems to be a useful criterion for defining fibroblasts and should be at least as accurate as currently existing morphological criteria. The membrane definition possibly has the additional advantage of defining subpopulations of fibroblasts in so far as collagens from different organs, such as skin or cartilage, are structurally different[21] and have different antigenicities[22]. These differences may be found in membrane-bound collagen, analogous to the phenomenon of allelic exclusion in B cells[23].

The presentation and mobility of collagen in the cell membranes of fibroblasts suggest several possible events in the biology of these cells. Capping of collagen may lead to the secretion of fibroblast cell product into the intracellular matrix. This theoretical consideration is strengthened by a recent observation that anti-fibroblast antibodies stimulate the secretion of trichloroacetic acid-precipitable cell product by fibroblasts[11]. Also, antibodies to chemically coupled substances on fibroblast cell membranes have been shown to cause a type of immunostimulation as measured by the incorporation of tritiated thymidine[24]. The presence of collagen in cell membranes could place fibroblasts at risk for immunologically mediated cytotoxic or suppressor reactions. We are studying these possibilities.

We thank Dr A. J. Bailey, ARC Meat Research Institute, Langford, Bristol for the collagen amino acid analysis.

Endotoxin-sensitive membrane component of human platelets

GRAM-NEGATIVE bacteria produce endotoxin and cause intravascular coagulation, shock and ultimate death of an estimated 25% of patients with bloodstream infections[1,2]. The number of blood platelets in such patients decreases[3]. In animal experiments, endotoxin aggregates platelets, induces release of vasoactive amines and adenine nucleotides, and unmasks the phospholipid procoagulant (platelet factor 3, PF3), which accelerates blood clotting[4]. To determine the mechanism of endotoxin action in man we studied the endotoxin interaction with human platelets. Here we describe experiments which demonstrate that the endotoxin-sensitive component (receptor) is present on the membrane of human platelets. Two types of changes resulting from endotoxin interaction with this receptor have been noted: selective release of 5-hydroxytryptamine (5-HT) and unmasking of platelet phospholipid (PF3).

Human platelets rendered free of plasma proteins (see Table 1) were sensitive to endotoxin. Addition of endotoxin in the form of *Salmonella enteritidis* lipopolysaccharide B (Difco, Detroit, Michigan) at a concentration of 200 µg per ml human platelets caused release of ^{3}H-5-HT. In 21 separate experiments release of 5-HT ranged from 37% to 81% with a mean of 59±2.8%. This was significantly more ($P<0.01$) than release of 5-HT from human platelets incubated in the same conditions without endotoxin 21 ±0.8%). 5-HT release from the control platelets can be explained by the observation that newly absorbed 5-HT behaves usually as endogenous amine, although it has a tendency to be somewhat more preferentially released[7]. In the protein-free medium used here this phenomenon could be accentuated notwithstanding the fact that gel-filtered platelets seem to preserve their functional and ultrastructural integrity[8]. In these conditions the amount of 5-HT released by endotoxin consistently exceeded two or three times control values. Release of 5-HT was selective as the cytoplasmic marker enzyme, lactate dehydrogenase, was not liberated indicating that no significant lysis of human platelets occurred. The lysosomal marker enzyme, β glucuronidase was also not released. 5-HT release was, however, paralleled by release of adenine nucleotides, determined spectrophotometrically[9]. This suggests that platelet-dense granules containing 5-HT and adenine nucleotides were

Table 1 Effect of homogenate of human platelets or their membrane-rich preparation on endotoxin-induced ^{3}H-5-HT release from autologous platelets

Reaction mixture	% ^{3}H-5-HT release (mean ± s.e.m.)
Endotoxin + buffer + platelets	66.0±2.1
Endotoxin + homogenate* + platelets	46.6±2.8†
Endotoxin + MRP + platelets	45.7±0.7†
Buffer + homogenate + platelets	28.3±1.3
Buffer + platelets (control)	24.6±1.4

Human platelets, collected from fasting venous blood of healthy individuals who had not ingested aspirin or aspirin-like drugs during the preceding 8 d, were labelled with ^{3}H-5-HT added to platelet-rich plasma. Platelets were freed from plasma proteins and from unbound ^{3}H-5-HT by gel filtration according to the modified procedure of Tangen et al[5]. using a column containing Sepharose 2B. Platelets containing ^{3}H-5-HT were eluted in the void volume of the column and plasma proteins were distinctly separate from platelets in the elution profile. Separation of platelets from plasma proteins was further documented immunochemically using a panel of antisera to whole human serum, human gamma globulin, C3 component of complement and properdin factor B (C3 activator). Gel-filtered platelets gave negative results with these antisera in the rocket immunoelectrophoresis[6], whereas fractions containing plasma proteins were consistently positive.

*Homogenate was prepared by six cycles of freezing and thawing of gel-filtered human platelets not labelled with ^{3}H-5-HT.

MRP (membrane-rich pellet) was prepared from homogenate by centrifugation at 20,000g for 20 min and resuspending in 1 ml Tris-buffered saline pH 7.4. MRP was free of lysosomal β glucuronidase and lactate dehydrogenase, which were released to soluble fraction (supernatant).

Endotoxin (200 μg) was preincubated with 1 ml homogenate or MRP for 30 min at 37 °C and then gel-filtered autologous platelets labelled with ^{3}H-5-HT were added. After 30 min of incubation samples were centrifuged at 15,000g for 1 min at 0 °C and radioactivity in the supernatant was determined.

†Difference significant compared with reaction mixture containing endotoxin, buffer and platelets: $P < 0.01$.

selectively responding to endotoxin-induced membrane changes.

To establish that endotoxin effect on human platelets was specific, zymosan, another particulate material derived from yeast cell wall, and human erythrocyte stroma as a membrane particulate material were compared in concentrations similar to that of endotoxin. In contrast to endotoxin, neither zymosan nor red cell stroma caused a significant release of ^{3}H-5-HT from human platelets rendered free of plasma proteins. These data suggest that endotoxin has a specific affinity for the membrane of human platelets inducing a selective release reaction.

Experiments were carried out to determine whether the ability of human platelets to bind endotoxin plays a part in this interaction. Endotoxin was preincubated with a homogenate of unlabelled human platelets or with buffer. Then, fresh autologous human platelets labelled with ^{3}H-5-HT were added and ^{3}H-5-HT release was measured as an index of endotoxin activity. Human platelet homogenate significantly inhibited endotoxin interaction with intact platelets (Table 1) measured by release of ^{3}H-5-HT ($P<0.01$). When the membrane-rich fraction sedimented from human platelet homogenate was tested, a similar inhibition of endotoxin-induced release was observed. These experiments suggest that human platelets contain an endotoxin-binding component (receptor) associated with their membrane.

Interaction of endotoxin with human platelet receptor induced not only selective release of ^{3}H-5-HT but also unmasked platelet phospholipid (PF3), thus accelerating blood clotting. Evolution of PF3 activity in human platelets was measured by shortening of the Stypven time[10]. Human platelets were incubated for 30 min at 37 °C with endotoxin or with buffer and then the mixture was added to the autologous platelet-poor plasma in which Stypven time was measured. In three separate experiments endotoxin incubated with human platelets caused a significant ($P<0.01$)

shortening of the Stypven clotting time of human platelet-poor plasma (34.5±1.2 s) compared with plasma to which human platelets incubated without endotoxin were added (46.6±2.3 s).

As PF3 is associated with platelet membrane phospholipids[11] its evolution represents another example of platelet membrane-related biological activity of endotoxin.

Endotoxin seemed to interact directly with a sensitive component of human platelet membrane. Human platelets rendered free of immunochemically detectable plasma proteins, were treated with trypsin (Nutritional Biochemical, 2 μg ml^{-1}), known to destroy IgG and complement adsorbed to platelets[12,13]. This did not abolish the ability of human platelets to interact with endotoxin. Addition of heparin or hirudin as inhibitors of thrombin in concentration of 10 IU ml^{-1} did not interfere with endotoxin-induced release of ^{3}H-5-HT. This provided further evidence that adsorbed plasma proteins, if present, were not required in our experimental system. Second, experiments with neutralisation of the endotoxin effect by a membrane-rich preparation obtained from autologous human platelets suggest the existence of an endotoxin-binding component (receptor) on the human platelet membrane. When the receptor is triggered by endotoxin, release of vasoactive amine, 5-HT, and evolution of clot-promoting PF3 activity ensues. Thus, in addition to the well known indirect pathway of activation of human platelets by microbial antigens complexed with antibody and/or complement and interacting with platelets through receptors for IgG Fc fragment and complement[14,15], there is a direct pathway of human platelet activation as a result of the existence of a specific endotoxin-sensitive component (receptor) (Fig. 1).

Endotoxin-binding component (receptor) may be added to the list of previously reported receptors on the human platelet membrane. They include receptors for ADP (ref. 16), 5-HT (ref. 17), IgG fragment[9] and thrombin-sensitive protein[18]. The presence of an endotoxin-binding component on cells of human origin is not limited to the platelets. Endotoxin is known to interact directly, in the absence of serum, with polymorphonuclear leukocytes[19] and with red blood cells, to which it can be bound[20]. Endotoxin-sensitive component (receptor) on human platelets as demonstrated in our study is important as platelets are intimately involved in the activation of blood coagulation, and their interaction with endotoxin may help us to understand better endotoxin-induced intravascular coagulation and shock in man.

Characterisation of the bacteriophage T4 receptor site

THE fundamental importance of specific cellular interaction is indicated by its ubiquity in biological systems. Such specificity must be mediated by macromolecular recognition of intrinsically the same nature as enzyme–substrate binding and antigen–antibody interactions, but few systems involving recognition between two cells or two organisms are readily amenable to investigation at the molecular level. The attachment of bacteriophage to its host is an exception, and the chemical constitution of the specific receptor site involved in the initial binding of phage T4 to *Escherichia coli* B has therefore been examined.

The T-even bacteriophages adsorb to their host bacteria initially by the tail fibres[1], and there are strong indications that this interaction determines the specificity of adsorption and thus delineates the possible host range of the phage[2-4]. The initial receptor site for phage T4 is situated in the host lipopolysaccharide[5-7], but apart from the demonstration that T4-resistant *E. coli* mutants lack UDPG pyrophosphorylase[8,9] the receptor has not been characterised further. The *E. coli* B lipopolysaccharide consists only of the core region, and a recent analysis[10] indicates that in this strain the major carbohydrate components of the core lipopolysaccharide are heptose, glucose and glucosamine; some pentose was also detected. An assay was devised to determine which of these components acts as receptor site for phage T4, and its linkage to the rest of the lipopolysaccharide.

The interaction of T4 with washed *E. coli* B cells was determined in the simplest medium which permits adsorption, in the presence of a variety of mono-, di- and tri-saccharides. Any sugar mimicking the whole or part of the phage receptor site should inhibit adsorption of the phage to the cell wall. Sugars unrelated to the receptor would have little effect. A similar approach has been used in studying the antigenic determinants of complex polysaccharides, but it has not hitherto been applied to analysis of specific interactions between organisms.
Fig. 1 Effects of D-glucose and D-fructose on bacteriophage T4 adsorption to *E. coli* B. Washed bacteria (5×10^8 cells ml^{-1}) and phage T4 (10^7 phage ml^{-1}) were mixed in 0.01 M Tris buffer, pH 7.8, containing 0.1 M NaCl at 30 °C. At intervals samples were centrifuged to remove bacteria and unadsorbed phage titred. ●, No sugar added; ○, 0.6 M D-glucose added; ▲, 0.6 M D-fructose added.

The effects of fructose, which is not a component of the *E. coli* cell wall, and glucose on adsorption of T4 are illustrated in Fig. 1. Glucose completely inhibits the adsorption, while the effect of fructose is much less dramatic and apparently nonspecific. Glucose or a related molecule therefore constitutes an essential part of the phage receptor site.

In order to determine the exact structural specifications at this site, the effects on phage adsorption of some of the epimers and derivatives of glucose were examined (Table 1). The ineffectiveness of mannose as an inhibitor indicates that the configuration at C-2 must be specifically that of glucose. Similarly the inability of galactose to inhibit binding demonstrates the importance of the configuration at C-4. Xylose had no effect on adsorption and although glucuronic acid did inhibit binding it was less effective than glucose, suggesting an absolute requirement for the C-6 group and a preference for —CH$_2$OH rather than —COOH at this position. Substitution or replacement of the glucose hydroxyl groups, unlike configurational change, frequently gave molecules which were effective antagonists of phage binding. This is true of the C-1, C-2 and C-3 positions, for glucosamine, N-acetylglucosamine, 2-deoxyglucose, 3-O-methylglucose and 1 : 5-gluconolactone all completely inhibited adsorption. Thus an aldohexose with configurations at C-2 and C-4 which are specifically those of glucose is the essential unit constituting the phage T4 receptor site. Glucose is the only naturally occurring sugar in this configuration, and it may be present as the hexose, glucosamine or N-acetylglucosamine, or as some more unusual derivative substituted at C-1, C-2 or C-3.

Although glucose is probably a component of all lipopolysaccharide molecules[11], bacteriophage T4 has an extremely narrow host range and does not adsorb to many Gram-negative organisms otherwise capable of supporting its growth[12]. On the basis that this specificity probably arises from the presence of a particular linkage in the lipopolysaccharide, the effects of a variety of di- and tri-saccharides

Table 1 Effects of mono-, di- and trisaccharides on adsorption of phage T4 to *E. coli* B

Monosaccharide	Inhibition of adsorption (%)	Di- or trisaccharide	Inhibition of adsorption (%)
D-Glucose	100	Sucrose	100
D-Galactose	< 1	Trehalose	100
D-Mannose	< 1	Maltose	100
D-Xylose	< 1	Turanose	100
D-Glucosamine	100	Kojibiose	100
N-Acetyl-D-glucosamine	100	Cellobiose	< 1
2-Deoxy-D-glucose	100	Lactose	< 1
3-O-Methyl-D-glucose	100	Melezitose	100
1 : 5-D-Gluconolactone	100	Raffinose	< 1
D-Glucuronic acid	10		

Adsorption curves (Fig. 1) were determined in the presence of 0.6 M sugar, after readjustment of pH to 7.8 when necessary. In all cases a plateau was reached between 6 and 12 min, and inhibition of adsorption was calculated from the number of unadsorbed phage at 12 min.

containing glucose were investigated (Table 1). Only those sugars in which glucose is α-linked to another residue inhibited adsorption; a β-linkage at C-1, as in cellobiose, rendered the molecule inactive. Moreover, linkage of a sugar residue to the C-4 or C-6 position of the glucose component in lactose and raffinose also destroyed activity. It appears that the glucose or glucose derivative acting as receptor for T4 must be α-linked to the rest of the lipopolysaccharide and cannot be bonded to another sugar residue through either the C-4 or C-6 hydroxyl groups.

Inhibition of binding should be more effective the closer the structure of the sugar inhibitor is to that of the receptor. Sugars which inhibit binding fell into three classes in terms of the dependence of degree of inhibition on sugar concentration (Fig. 2). All monosaccharides tested—glucosamine, N-acetylglucosamine, 2-deoxyglucose, 3-O-methylglucose and 1 : 5-gluconolactone—displayed the same concentration effect as glucose; the dependence of inhibition on sugar concentration did not therefore indicate whether glucose or one of its derivatives was the basic component of the T4 receptor site. Maltose was slightly more effective, and sucrose, turanose, kojibiose, trehalose and melezitose all inhibited binding at significantly lower concentrations than glucose. It seems that the nature and number of the sugars to which glucose is linked do not affect its activity as an inhibitor, but that the α1→4 linkage of glucose to glucose in maltose results in a less favourable configuration of the

inhibitor than the α1→1 or α1→2 linkage of glucose to glucose and the α1→2 or α1→3 linkage of glucose to fructose found in more effective inhibitors. Apparently, therefore, the glucose, glucosamine or closely related residue which acts as the T4 receptor may be in a terminal position α-linked to the 2- or 3-position of the adjoining residue, or it may be internally situated in the carbohydrate chain through linkages to its own C-2 or C-3 position. Determination of the exact structure of the receptor in *E. coli* B awaits sequencing of its lipopolysaccharide, but the value of this type of technique for partial determination and comparison of both phage receptors and bacterial surface structures is evident, as is its possible application to a wide variety of problems of intercellular recognition.

Fig. 2 Dependence of adsorption inhibition on sugar concentration. Adsorption curves (Fig. 1) were determined at different sugar concentrations, and inhibition of adsorption calculated from the number of unadsorbed phage at 12 min (Table 1). ○, D-glucose; D-glucosamine, N-acetyl-D-glucosamine, 2-deoxy-D-glucose, 3-O-methyl-D-glucose and 1 : 5-D-gluconolactone also gave this concentration curve. ●, Maltose; ▲, sucrose; the same curve was obtained with turanose, kojibiose, trehalose and melezitose.
Experimental autoimmune myasthenia induced in monkeys by purified acetylcholine receptor

MYASTHENIA GRAVIS (MG) is a neuromuscular junction disease of man characterised by muscular weakness and fatigability.

Evidence that an autoimmune response to the postsynaptic nicotinic acetylcholine receptor (AChR) is important in the pathogenesis of MG has recently been presented. We have demonstrated a specific sensitisation of lymphocytes from MG patients when cultured *in vitro* with an AChR fraction extracted from the electric organ of the electric eel[1]; we have further shown reduction of such sensitisation in lymphocytes from patients under steroid treatment displaying clinical improvement[2]. Fambrough *et al.*[3] have shown that there is a reduction in the number of junctional acetylcholine receptors in myasthenic muscles. Patrick and Lindstrom[4], Heilbronn *et al.*[5] and Aharonov *et al.*[6] induced experimental autoimmune myasthenia in rabbits by injection of AChR isolated from electric organ
Fig. 1 Myasthenic monkey one week after fourth injection of purified acetylcholine receptor. *a, b*, Before injection of Prostigmine; *c*, 5 min after injection of Prostigmine (0.2 mg); *d*, 10 min after injection of Prostigmine.

tissue of either the electric eel, *Electrophorus electricus* or the electric ray, *Torpedo*.

Here we describe the induction of experimental auto-immune myasthenia gravis in Rhesus monkeys by injection of AChR purified from the electrogenic tissue of *T. californica*. The clinical, pharmacological electrophysiological, immunological and histological findings in monkeys suffering from experimental autoimmune myasthenia closely parallel those in patients suffering from MG.

Purified AChR from electrogenic tissue of *T. californica* was obtained by solubilisation of membrane fragments with 1% Triton X-100, followed by affinity chromatography on a *Naja naja siamensis* neurotoxin–Sepharose resin, as described by Aharonov *et al.*[6], with slight modifications, for isolation of AChR from the electric eel. The specific activity of the purified AChR was 8,000–10,000 pmol toxin bound per mg protein.

Two female Rhesus monkeys, *Macaca mulatta* (3 kg), were injected in both foot pads and intradermally in 3–4 spots with 100–200 µg AChR in 0.5 ml saline mixed with 0.7 ml Freund's complete adjuvant (FCA). At three-week intervals, both animals were subsequently challenged three times with AChR administered in the same way. Control monkeys received FCA alone. Within two weeks of the third injection of AChR, the two monkeys showed signs of fatigue, hypoactivity, anorexia and weight loss. One week after the fourth injection the monkeys' condition was acute, with extreme flaccid paralysis of the limbs and trunk, sinking of the head and severe difficulties in breathing (Fig. 1*a* and *b*). Bulbar signs included ptosis, external ophthalmoplegia, facial diplegia and paralysis of the jaw muscles, with uncontrolled salivation and severe dysphagia. Shortly after intramuscular injection of 0.2 mg of the anticholinesterase Prostigmine (neostigmine bromide) the sick monkeys began to display signs of recovery which was complete within ten minutes: they became erect, raised their heads, placed their legs under their bodies, were able to move and essentially to breathe normally; at the same time, all bulbar signs disappeared (Fig. 1*c* and *d*). This improved condition was maintained for about 4 h. No clinical changes were observed in monkeys injected with FCA alone.

Neurophysiological studies were made on the animals after 6 weeks, before the fourth injection, using a Grass electromyograph with stimulator unit and differential amplifier. A coaxial recording electrode was introduced into the calf muscle and a bipolar stimulation electrode was placed on the buttock over the sciatic nerve. The electromyographic examination revealed a decrease in amplitude during repetitive nerve stimulation in AChR-injected monkeys (Fig. 2*a*) and a normal response in control animals (Fig. 2*b*).

After the pharmacological investigations and before the animals were killed, blood was collected by heart puncture and humoral antibodies against purified AChR were detected by the agar gel immunodiffusion assay in the sera of the animals (see Fig. 3). Cellular sensitivity towards

Fig. 2 Electromyographs from myasthenic and normal monkeys. Tetanic stimulation was carried out at a frequency of 40 s^{-1}, with pulses of 0.1 ms duration and 150 V amplitude. Horizontal bar, 2 s; vertical bar, 5 mV. *a*, Myasthenic monkey; *b*, Control monkey.
Fig. 3 Agar gel immunodiffusion of serum from a sick monkey. Well 1, monkey serum; well 2, purified acetylcholine receptor (300 μg ml^{-1}).

AChR was demonstrated in lymph node cells using the lymphocyte transformation technique (2-^{14}C-thymidine uptake) according to the method described by Tarrab *et al.*[7]. The results are expressed as stimulation indices (SI) (the ratio of radioactivity in tubes containing antigen to the radioactivity in control antigen-free tubes), and they represented an average of values obtained in duplicate cultures. Lymphocytes of myasthenic monkeys showed SI of 3.0, 12.5 and 12.8 when incubated in the presence of 0.5 μg, 1 μg and 2 μg AChR, respectively, and SI of 0.8–1.4 when incubated with other antigens such as rabbit actin, rat collagen and lysozyme. No stimulation was obtained in the control animals with either AChR (SI 0.9–1.3) or the other antigens (SI 0.8–1.4).

Samples of brain, thymus and muscles were taken for pathological examination. The formalin-fixed paraffin-embedded sections were stained with haematoxylin–eosin and light green. The histopathology revealed a few lymphocytes between muscle cells in the leg muscle and mild lymphorrhage foci in a buccal muscle (Fig. 4).

The clinical picture and the histopathological findings, as well as the characteristic clinical improvement after anti-cholinesterase administration and the pathognomonic decremental response to repetitive nerve stimulation, indicate that the monkeys suffered from myasthenia. The criteria for diagnosis of MG in patients suffering from criteria applied are closely analogous to the principal muscular weakness.

Fifteen years ago it was already suggested that MG

Fig. 4 Lymphorrhage focus in a buccal muscle section from a myasthenic monkey. Haematoxylin–eosin and light green. ×280.

might be an autoimmune disease of the neuromuscular junction[8,9]. Goldstein and coworkers[10], Kalden *et al.*[11] and Kawanami and Mori[12] attempted to provide an experimental model for the disease in experimental animals injected with either muscle or thymic extracts. Although electrophysiological evidence for a partial neuromuscular block was demonstrated, the animals did not show any clinical signs of muscle paralysis, and others were unable to confirm these findings[13–15]. Clinical as well as electrophysiological and pharmacological signs of myasthenia were recently induced by Patrick and Lindstrom[4] and subsequently by Heilbronn *et al.*[5] and ourselves[6] in rabbits immunised with AChR purified from electric fish. The nicotinic AChR of the electrogenic organ tissue of the electric fish is pharmacologically similar to the same receptor in skeletal muscle[16], and cross reacts immunologically with AChR from other species[4,17] and, as the present study suggests, most probably with monkeys as well. These findings thus provide supporting evidence that MG is an autoimmune disease and that AChR is the autoantigen. Our earlier observations[1,2] on a cellular immune response to AChR of lymphocytes from patients with MG provided direct evidence that breakdown of tolerance to self-AChR is involved in the neuromuscular block. The AChR-induced myasthenia in monkeys, so similar to the human disease, provides a valuable experimental model for studying both the mechanism and therapy of myasthenia gravis.

Anti-fertility drugs: novel non-hormonal compounds that inhibit prostaglandin metabolism

PREGNANCY has been terminated in animals and/or humans by oestrogens[1–3], androgens[4,5], anti-oestrogens[6,7] prostaglandins[8–10], and various non-steroidal non-hormonal agents[6–11].

Table 1 Subcutaneous doses of L10492 and L10503 for each of 5 consecutive days required for termination of pregnancy in 100% rats and hamsters

Animal	Treatment on gestation days	L10492	L10503
		(mg kg^{-1} d^{-1})	
Rat	1–5	25.0	100.0
	4–8	10.0	30.0
	6–10	2.5	20.0
	8–12	10.0	30.0
Hamster	1–5	2.0	0.5
	4–8	0.5	0.25
	6–10	3.0	1.5
	8–12	>10.0	>5.0

The mechanism of action of these agents has not been defined and effectiveness varies with the species. Elevated levels of endogenous prostaglandins (PGs) may be associated with toxaemia of pregnancy and habitual abortion[12]. PG may also alter foetal and placental blood flow[13,14]. A compound that inhibits PG metabolism—thereby elevating PG levels—could possibly interrupt pregnancy. This report describes a new class of non-hormonal compounds, which are 100% effective as anti-fertility agents in several species of animals, and also outlines studies on the effect of these compounds on PG synthesis and metabolism in rat placenta.

Compounds studied were 2-(3-methoxyphenyl)-5-H-s-triazolo [5,1-α] isoindole (L10492) and 2-(3-methoxyphenyl)-5,6-di-hydro-s-triazolo [5,1-α] isoquinoline (L10503). These compounds in sesame oil were administered subcutaneously to female Sprague–Dawley rats and Golden Syrian hamsters on various days after mating, the rats and hamsters were killed on days 16 and 14 of pregnancy, respectively, and the uteri examined for live or dead foetuses, implantation sites or resorpting foetuses.

Dose-related anti-fertility effects were obtained with both compounds when administered in various 5 d segments during the first half of gestation in both species (Table 1). The most effective time for treatment was during gestation days 6–10 in rats and days 4–8 in hamsters. Although 100% pregnancy termination was obtained in each treatment period, the most effective time for treatment was soon after implantation of the fertilised ova. Note that L10492 was more potent in rats and that L10503 was more potent in hamsters. The latter, however, was more sensitive to treatment with either compound. Single injections of these compounds also produced dose and time of pregnancy-related abortifative activity in both species (Fig. 1). Dose required for 100% effectiveness, however, was higher than that needed with multiple injections. The optimum time for drug administration was during days 4 or 5 in the hamster and days 7 or 8 in the rat, corresponding to the time immediately following implantation of the blastocyst in the uterus. As in the case of the multiple injection studies, the hamster was the more sensitive species and L10492 was more potent in the rat than L10503; the latter was, however, more potent in the hamster.

Studies on the mechanism of action indicated that the primary site for drug action is at the utero–placental complex. Higher brain centres, hypothalamus, pituitary and ovaries are not required for the anti-fertility activity as rats ovariectomised on day 8 of pregnancy and maintained in the gravid state by daily subcutaneous injections of 10 mg progesterone plus 1 μg oestradiol benzoate, resorbed all their foetuses after a single 50 mg kg^{-1} injection of L10492. Similar results were obtained in both animal species with both compounds in several different treatment regimens. In addition pregnant rats administered single (days 7 or 8 of pregnancy) or multiple (days 6–10 of pregnancy) doses of L10492 (50 mg kg^{-1} single or 2.5 mg kg^{-1} d^{-1}) or L10503 (100 mg kg^{-1} single or 25 mg kg^{-1} d^{-1}) and progesterone at daily doses of 4 mg per rat on days 6–15 of gestation, resorbed the products of pregnancy. These treatments did not affect the corpora lutea which were well developed

and apparently functional during foetal resorption. Mechanism of action does not involve ovulation inhibition as treatment was initiated after ovulation and conception (Table 1 and Fig. 1). Also rats and hamsters treated with abortifative doses of each compound in various phases of their oestrous cycles ovulated normally. These compounds did not inhibit implantation of the fertilised ova as administration of L10492 or L10503 after ovulation and mating but before implantation allowed the ova to implant but subsequently the implants were resorbed (Table 1 and Fig. 1). Hormonal or anti-hormonal activity is not involved in the anti-fertility action of these agents as they are devoid of oestrogenic, anti-oestrogenic, androgenic, anti-androgenic, progestational or anti-progesterone activities.

The possibility that placental PG synthesis and metabolism was altered by drug treatment was investigated. Metabolism was studied as described previously[15]. Synthesis was studied using the method of Flower et al.[16] and modified as described in Table 2.

Placental PG metabolism varies with the day of pregnancy and is lowest on day 8, is sharply increased on day 11, returns to a low level on day 14 and then becomes maximal on days 16 to parturition. As the optimum time for anti-fertility activity of L10503 (100 mg kg^{-1}, subcutaneously) was found to be on days 7, 8 or 9 of gestation[17], we studied the effect on placental PG metabolism on days 8, 9 and 10 and on PG synthesis on day 9. L10503 inhibited PG metabolism on a per mg protein basis, the degree of inhibition being dependent on the day of drug treatment. In the case of PGE_1 there was no alteration in metabolism when the compound was administered on days 8, 9 or 10 of gestation but when treatment was on both days 9 and 10 there was a 48% inhibition of metabolism. $PGF_{2\alpha}$ metabolism, however, markedly decreased when L10503 was injected on days 8, 9 or 9 and 10 but a single injection on day 10 produced no significant change in placental $PGF_{2\alpha}$ metabolism. Administration of this drug on days 9 and 10 resulted in a 68% decrease in $PGF_{2\alpha}$ metabolism; thus L10503 is a more potent inhibitor of $PGF_{2\alpha}$ metabolism than PGE_1 metabolism. Not only did this compound affect PG metabolism but it also reduced placental weight when administered on days 8, 9 and 10 of pregnancy, the greatest effect resulting from

Fig 1 Abortifacient activity of single subcutaneous injections of L10503 (a, c) or L10492 (b, d) on various days during the first 11 d of pregnancy in rats and hamsters. a: ———. 25 mg kg^{-1}; – – – –, 6.25 mg kg^{-1}; – . – . – ., 1.56 mg kg^{-1}. b: ———, 25 mg kg^{-1}; – – – –, 12.5 mg kg^{-1}. c and d: ———, 100 mg kg^{-1}; – – – –, 50 mg kg^{-1}.

Values are mean ±s.e. of three pools of placentae from 4–8 rats each. Placentae preserved at −30 °C, homogenised in Bucher medium, 1:5 (w/v) for $PGF_{2\alpha}$ metabolism and 1:10 (w/v) for PGE_1 metabolism studies, and centrifuged at 10,000g for 15 min. To 2 ml aliquots of the supernatant were added 4 mM NAD^+, 0.1 μM $PGF_{2\alpha}$ (2.25 Ci $mmol^{-1}$) or 0.1 μM PGE_1 (2.45 Ci $mmol^{-1}$). Incubation time at 37 °C was 20 min for $PGF_{2\alpha}$ and 5 min for PGE_1 metabolism. Enzymatic reaction was stopped by addition of 0.2 ml 1 N HCl to acidify at pH 3.0. Extraction and separation by thin-layer chromatography of prostaglandins and their metabolites (15-keto and 15-keto-dihydro derivatives) were performed as described previously[15]. For PG synthesis studies, tissues were homogenised with 0.1 M Tris-HCl buffer pH 8.2, 1:5 (w/v). To 2 ml aliquots were added 4 mM adrenaline, 4 mM glutathione, and 1 μM ^{3}H-arachidonic acid (0.53 Ci $mmol^{-1}$). Time of incubation was 1 h and reaction was stopped by addition of citric acid to acidify at pH 3.0. Extraction and separation by thin-layer chromatography was as described previously[16].

Significance between treated and control groups was determined using Dunnett's t test; an F test following analysis of variance was used to compare data between experimental groups. *$P < 0.01$ and †$P < 0.05$ against vehicle control group; ‡$P < 0.01$ against day 9 treatment group; §$P < 0.01$ against day 10 treatment group.

treatment on both days 9 and 10. Note that even though placental weight was reduced by treatment, the concentration of protein per 100 mg tissue was unaffected (6.94±0.13 mg, mean ±s.e.). PG metabolism was therefore computed on the basis of total placental weight (Table 2). Treatment on any of the three pregnancy days studied resulted in significant reductions in PGE_1 metabolism. L10503 administered on days 9 and 10 decreased PGE_1 metabolism by 67%, and an even greater suppression of $PGF_{2\alpha}$ metabolism was observed after single day treatments on each of the three days of pregnancy. Administration of the compound on days 9 and 10 resulted in a 79% reduction in $PGF_{2\alpha}$ metabolism. *In vitro* studies also showed that L10503 inhibited $PGF_{2\alpha}$ metabolism although PGE_1 metabolism was unaffected.

PGE_2 and $PGF_{2\alpha}$ synthesis in the placenta was not significantly altered when L10503 (100 mg kg^{-1} subcutaneously) was administered on day 9 of pregnancy. PGE_2 synthesis in this tissue was four to five times greater than $PGF_{2\alpha}$ synthesis.

These studies on PG metabolism indicate that the mechanism of anti-fertility action of L10503 may involve the inhibition of placental PG metabolism, leading to an elevated level of endogenous PG which could be detrimental to placental physiology, that is, altered haemodynamics.

The toxicity (LD_{50}) of L10492 and L10503 is very low compared with the abortifacient doses (ED_{100}) when the compounds were administered for 5 consecutive days. The toxic dose was greater than 64 times and >320 times more than the ED_{100} doses for rat and hamster, respectively, in the case of L10492, and >8 times and >640 times more than the ED_{100} doses for rat and hamster, respectively, in the case of L10503.

High but not abortifacient doses of these anti-fertility agents have not produced teratogenic effects. Animals whose pregnancies were terminated with these drugs promptly returned to normal oestrous cycles, mated, became pregnant, had normal litters and lactated normally. The offspring resulting from these pregnancies were fertile at maturity.

These studies indicate that L10492 and L10503 are safe and effective anti-fertility agents that may produce their effect by inhibiting endogenous PG metabolism in the placenta. Furthermore these compounds may be useful in elucidating the role of PGs and their metabolism in placental function.

Non-antiviral activities of interferon are not controlled by chromosome 21

USING mouse–human cell hybrids, Tan *et al.*[1] assigned the gene(s) for the expression of the antiviral state induced by human (leukocyte) interferon to chromosome 21; furthermore, human skin fibroblasts trisomic for chromosome 21 proved more sensitive to the antiviral activity of human (leukocyte) interferon than normal diploid fibroblasts or trisomic 18 or 13 fibroblasts[2,3]. Since the non-antiviral and antiviral activities of interferon remain inseparably linked through approximately a million-fold purification (ref. 4 and references cited therein), the question may be raised

whether these various activities of interferon are accounted for by the same mechanisms and whether the expression of the non-antiviral activity of (human) interferon is also controlled by chromosome 21.

We report here that—in comparison with normal diploid (D) cells, or trisomic 18 (T-18) or trisomic 13 (T-13) cells—trisomic 21 (T-21) cells are indeed more sensitive to the antiviral action but not to the non-antiviral effects of interferon. As parameters of the non-antiviral activity of interferon we chose 'priming' (increased responsiveness of interferon-treated cells to interferon induction by poly(I)·poly(C)[5,6]) and 'toxicity-enhancement' (increased susceptibility of interferon-treated cells to the cytotoxicity of double-stranded RNAs[7,8], such as poly(I)·poly(C)). Both the antiviral and the non-antiviral activities of interferon were explored with human leukocyte and fibroblast inter-

Fig. 2 Toxicity-enhancing activity of human leukocyte (*a*) and fibroblast (*b*) interferon in normal diploid fibroblasts (NS, JH) and fibroblasts trisomic for chromosome 13, 18 or 21. Semi-confluent cell cultures in 60 mm Falcon Petri dishes were treated with interferon at the indicated concentrations (in Eagle's MEM + 3% foetal calf serum: 2 ml per Petri dish) for 16 h at 37 °C, drained, washed, and then exposed to 100 µg ml⁻¹ of poly(I)·poly(C) (P-L Biochemicals, Milwaukee, Wisconsin) (in Eagle's MEM, 1 ml per Petri dish) for 1 h at 37°C. The plates were then washed and further incubated with serum-free Eagle's MEM (4 ml per Petri dish) for 16 h, at which time toxicity was monitored by neutral red uptake[7]. Symbols represent mean values for three experiments. ●, NS; ▲, JH; ○, T-13; △, T-18; □, T-21.

Fig. 1 Antiviral activity of human leukocyte (*a*) and fibroblast (*b*) interferon in normal diploid fibroblasts (two cell lines, designated NS and JH, respectively) and fibroblast trisomic for chromosome 13, 18 or 21. Wells of a semi-micro Linbro plate were seeded with 10^5 cells ml⁻¹ (Eagle's MEM + 10% foetal calf serum) per well. When confluent (usually after 4 d), the cells were maintained for another 3 d in EMEM + 3% foetal calf serum. The cultures were then treated with our standard leukocyte or fibroblast interferon preparations, diluted (in EMEM + 3% foetal calf serum) to give approximately 1.5 $\log_{10}$ units ml⁻¹ in NS cells, for 16 h at 37 °C, drained, washed, challenged with Mengo virus and further processed by the neutral red uptake technique as described by Finter[27]. The amounts of stain incorporated were determined by optical density readings at 542 nm. The readings made for the virus controls did not differ significantly from one cell type to another; nor did the readings made for the different cell controls. Hence, gross differences in normal cell metabolism or virus replication pattern between the different cell types employed may be excluded. Bars show means (+ s.d.) for three experiments.

feron preparations. Our studies indicate that, unlike the antiviral activity, the non-antiviral effects of human leukocyte and fibroblast interferon are not genetically determined, or at least not by chromosome 21.

Human leukocyte and fibroblast interferon were prepared according to well-established procedures[9,10]. The leukocyte and fibroblast interferon preparations employed had specific activities of approximately 10^4 units per mg protein. Interferon titres are expressed in terms of the British Research Standard B for human interferon (69/19). Fibroblast cultures were established from skin biopsies. The cells were subcultured in Eagle's minimal essential medium (MEM) supplemented with 10% foetal calf serum. All cell cultures were matched as nearly as possible with regard to the number of cell generations in culture.

In agreement with Tan's findings[2,3], our experiments showed that T-21 cells were about ten times more sensitive

to the antiviral action of human leukocyte intereferon than either T-13 or T-18 or normal diploid cells (Fig. 1). In addition, T-21 cells were more sensitive than T-13, T-18 or diploid cells to the antiviral action of human fibroblast interferon (Fig. 1).

The inhibitory effect of poly(I)·poly(C) on virus multiplication is thought to be mediated by interferon induction even at polymer concentrations which do not lead to the release of detectable amounts of interferon in the cell culture medium[11-13]. If this assumption is correct, one may expect poly(I)·poly(C) to be more active in inhibiting virus replication in T-21 than in normal diploid cells. As shown before[2], poly(I)·poly(C) was indeed more active in T-21 than in normal diploid cells: the minimal concentration of poly(I)·poly(C) required to suppress cytopathogenicity induced by vesicular stomatitis virus was 0.003 µg ml⁻¹ in T-21 cells but 0.03 µg ml⁻¹ in three normal diploid cell lines (designated NS, JH and FS-4).

In accord with previous findings[7], human fibroblast interferon enhanced the susceptibility of human fibroblasts to the toxicity of poly(I)·poly(C) (Fig. 2). The extent of cell destruction, as monitored by neutral red uptake, closely paralleled the amounts of interferon applied. Leukocyte interferon proved equally effective as fibroblast interferon in enhancing the toxicity of poly(I)·poly(C). Most importantly, all cell lines tested, whether disomic or trisomic, behaved quite similarly in their sensitivity to the toxicity-enhancing activity of interferon (Fig. 2).

Similar results were obtained with regard to the priming activity of interferon (Fig. 3) : no marked differences were noted in the sensitivities of T-13, T-18, T-21 and normal diploid cells to the priming effect of either human leukocyte or fibroblast interferon.

Two major conclusions follow from these results. First, though the antiviral activity of human leukocyte and fibroblast interferon seems to be controlled by gene(s) located on chromosome 21, their non-antiviral activities are not. It is even arguable whether the non-antiviral activities of interferon are genetically regulated at all. On several occasions it has been suggested, albeit without direct experimental evidence, that the priming as well as the toxicity-enhancing effect of interferon are solely cell surface (or
Fig. 3 Priming activity of human leukocyte (*a*) and fibroblast (*b*) interferon in normal diploid fibroblasts (NS) and fibroblasts trisomic for chromosome 13, 18 or 21. The procedure followed for measuring the priming activity of interferon diverged from that applied for measuring the toxicity-enhancing activity (legend to Fig. 2) in that confluent (instead of semiconfluent) cell cultures were used (about 5×10^6 cells per Petri dish), poly(I)·poly(C) was added at 50 (instead of 100) μg ml^{-1}, and the plates were incubated with Eagle's MEM+3% foetal calf serum (instead of serum-free medium) after their exposure to poly(I)·poly(C). The supernatant fluids collected 16 h after poly(I)·poly(C) had been removed were assayed for interferon by the dye uptake method[27] in human skin fibroblasts (NS) challenged with Mengo virus. The interferon titres are expressed as the differences in titre obtained between the 'primed' and control cell cultures. ●, NS; ○, T-13; △, T-18; □, T-21.

cell membrane) phenomena[8,14,15]. The data presented here and previous data[5,8], eliminating the necessity of protein synthesis for the expression of the priming and toxicity-enhancing effects of interferon, would seem consistent with this hypothesis. Although the data reported here indicate fundamental differences in the mechanisms underlying the antiviral and non-antiviral activities of interferon, they do not rule out the possibility that these mechanisms only diverge from a certain point onward: for example both the antiviral and non-antiviral effects of interferon may be triggered from the cell surface[16–18]. Whereas the 'priming' and toxicity enhancement could be envisaged as the direct consequence of an alteration of the cell membrane, the expression of the antiviral state would require a few additional steps involving derepression, transcription and, finally, translation of the putative antiviral protein.

Second, human leukocyte interferon and human fibroblast interferon differ considerably in their biological properties (antiviral activity in heterologous cells[19–21]), physicochemical properties (stability towards heat[22], shaking[23], guanidine treatment[23], reactivation by anionic detergents[24]) and antigenic properties (as assessed by neutralisation with specific antisera[25,26]). These differences may imply that human leukocyte interferon and human fibroblast interferon differ structurally[25] and/or contain distinct molecular species[24], and, if our interferon preparations contain different molecular species, the question arises whether the antiviral and non-antiviral activities of the interferon preparation reside in one and the same or in separate molecular species. Yet, in spite of these differences, leukocyte and fibroblast interferon exhibited similar antiviral, priming and toxicity-enhancing activities in the fibroblast cell lines studied. Hence, human leukocyte interferon and human fibroblast interferon should share a common structural determinant that initiates both the antiviral and non-antiviral responses (possibly from a common receptor site at the cell surface, as suggested above).

We thank Mrs A. Van Lierde, Mrs M. Stuyck, Miss I. Ronsse, Miss M. Scheys and Mrs G. Koninckx for technical

Saturable, energy-dependent, transmembrane transport of prostaglandins against concentration gradients

SOME vertebrate tissues, such as the choroid plexus, anterior uvea, and the kidney cortex, accumulate radioactivity against a concentration gradient when incubated with ^{3}H-prostaglandins (^{3}H-PGs)[1]. This accumulation is reversible, temperature-dependent and can be inhibited by metabolic and transport inhibitors, and by high concentrations of PGs, PG analogues and some organic acids such as probenecid and indomethacin[2,3].

It has been argued[1] that *in vitro* accumulation of PGs by the choroid plexus and anterior uvea reflects the transmembrane transport of these biologically active fatty acids across the blood–brain and blood–ocular fluid barriers. Such active PG absorption from the extracellular fluids of brain and eye could have considerable physiological significance as these potentially harmful autocoids are produced, but not effectively metabolised, by intraocular[4] and central nervous tissues[5]. Recent experiments have shown that rabbit erythrocytes are impermeable to PGs of the E and F series, indicating that cellular membranes can represent effective barriers to the free diffusion of these autocoids[6]. We must consider therefore that the elimination of PGs from the extracellular fluids of eye and brain, the intracellular metabolism of PGs by the lung, and their excretion by the kidneys require specific transmembrane transport processes[7].

In vivo experiments have already provided evidence that

PGs are transported out of the intraocular[8] and cerebrospinal[9] fluids and are absorbed from the vaginal lumen[10] of rabbits by facilitated, carrier-mediated mechanisms. None of these *in vivo* experiments, however, could provide direct evidence for active transport of chemically unaltered PGs as the rapid metabolism of PGs by lung and liver prevents the chemical identification of the transported PGs and the maintenance of constant PG concentration in the blood. Whereas *in vitro* studies demonstrated that PG uptake against a concentration gradient is not primarily associated with a chemical alteration of the PG
Fig. 1 Unidirectional ^3H and ^{14}C fluxes across isolated rabbit vagina. *a*, M_i to M_o fluxes. Initially M_i contained ^3H-PGF$_{2\alpha}$ (●) plus PGF$_{2\alpha}$ (total [PGF$_{2\alpha}$] = $10^{-6}M$) plus ^{14}C-sucrose (○), whereas M_o contained no PG or radioactivity. Rapid outward movement of ^3H activity reversed initial ^3H gradient within 90 min. *b*, M_o to M_i fluxes. Initially M_i contained no radioactivity and no PG whereas M_o contained ^3H-PGF$_{2\alpha}$ (as above; ●) plus ^{14}C-thiourea (○). Entry of ^3H-PGF$_{2\alpha}$ into the tissue resulted in some ^3H loss from M_o, but there was no evidence of ^3H-PGF$_{2\alpha}$ entry into the lumen. In contrast, ^{14}C-thiourea, a substance which freely penetrates cell membranes, rapidly crossed the tissue and a thiourea equilibrium between M_o and M_i was approached within 2 h.

New Zealand white rabbits (2.1–3 3 kg) were killed with an overdose of Nembutal. The vagina was freed by blunt dissection and cut near the pelvic bone and just below the cervix. One end of the resulting tube was fitted with, and tied to, a Plexiglass tube and the other end was ligated to form a bladder-like preparation. The resulting sac was filled with 1 or 2 ml Earle's tissue culture medium (Microbiological Associates) and was lowered into a vessel containing 2 ml culture medium. The Plexiglass tube served as a reservoir for the inside medium during the periods of vaginal constrictions which typically lasted for 10 s with a periodicity of 0.5 to 3 min To minimise variations in results, only vaginas which could be fitted over the 8 mm diameter tip of the Plexiglass tube and the walls of which were translucent, and less than about 2 mm thick in the relaxed state, were used. As the surface areas of these bladder-like preparations could not be accurately determined, individual rates could not be standardised to a unit surface area. Each figure represents, therefore, results obtained on one preparation, typical of a set of four or more similar experiments The assembly was maintained in a bath at 37 °C or at 2–4 °C. In most experiments, trace amounts of ^{14}C-sucrose, ^{14}C-thiourea, ^{14}C-octanoic acid or ^{14}C-linoleic acid were also added to either M_o, M_i, or both, to test the passive permeability properties of the vagina and the specificity of this transport system Samples (20 µl) of both M_o and M_i were taken at 5–20 min intervals, oxidised using a Packard Tricarb Model 306 automatic sample oxidiser, and the separate ^3H and ^{14}C samples counted for 10 min or 10,000 counts in a liquid scintillation counter. In some experiments both media were changed, after 60 or 90 min, to one containing a high concentration of unlabelled PG, or another potential inhibitor, in addition to the ^3H and ^{14}C-labelled compounds After 30–50 min of further sampling, both inside and outside compartments were washed with, and replaced by, a medium containing a higher inhibitor concentration or with the original, inhibitor-free, radioactive medium.

molecule[11], such uptake studies could not distinguish between PG adsorption on to specific binding sites and active transport of free PGs into interstitial fluid compartments.

In the present experiments, a bladder-like preparation of the isolated rabbit vagina was used as a model system to demonstrate that chemically unaltered PG can indeed be transported across a biological membrane against a chemical concentration gradient by a temperature and energy-dependent, saturable process.

Either the inside (M_i) or the outside (M_o) or both media contained ^3H-PGF$_{2\alpha}$ or ^3H-PGE$_1$ (New England Nuclear) and both sides were aerated with 95 % O_2, 5 % CO_2.

In experiments in which initially only M_i contained ^{14}C-sucrose and ^3H-PGF$_{2\alpha}$, there was a rapid entry of ^3H into M_o, but there was no significant loss of ^{14}C from M_i or detectable entry of ^{14}C into M_o. The results of a typical experiment are shown in Fig. 1a. In four identical experiments, the observed $M_i \rightarrow M_o$ ^3H transfer corresponded to a total apparent PGF$_{2\alpha}$ flux of 400 ng h^{-1}. Thus, the rabbit vagina, presumably its epithelial lining, allows a rapid flux of PGF$_{2\alpha}$ in the outward direction, yet it is a permeability barrier to sucrose, a substance of essentially identical molecular weight.

When initially only M_o contained ^3H-PGF$_{2\alpha}$, there was an initial decrease in ^3H activity of M_o in all five such experiments, presumably due to the entry of ^3H-PGF$_{2\alpha}$ into the tissue itself, but there was no detectable entry of ^3H activity into M_i. The result of a typical experiment of this series is shown in Fig. 1b. Thus, the rabbit vagina is an effective barrier to the influx of PGF$_{2\alpha}$ into the lumen while allowing a large PGF$_{2\alpha}$ efflux from the lumen to the outside. This outward ^3H flux could not be caused by passive ^3H-PGF$_{2\alpha}$ diffusion only, as after the first 90 min of incubation, the ^3H concentration in M_o surpassed that of M_i (Fig. 1a).

When the vagina was inverted before insertion of the cannula, the direction of the net ^3H flux remained 'mucosal' →'serosal'. Experiments with ^{14}C-linoleic or ^{14}C-octanoic acid showed no evidence of transmembrane transport of these unrelated fatty acids.

When initially both M_o and M_i contained the same ^3H-PGF$_{2\alpha}$ concentration, the ^3H activity of M_i steadily decreased, whereas that of M_o showed a continuous increase between 10 and 60 min of incubation. This resulted in the establishment of a continually increasing ^3H gradient across the isolated vagina reaching a more than 18-fold gradient by 2 h incubation at 37 °C (Fig. 2a). The mean ^3H gradient in five such experiments was 5.2 ± 0.8 ($n = 13$) at the end of 1 h, reaching a peak of 14 ± 4 ($n = 4$) at 3 h incubation at 37 °C. Similar results were obtained when ^3H-PGE$_1$ was used instead of ^3H-PGF$_{2\alpha}$, but the extent of the maximum ^3H gradient was lower (three to sevenfold between 2 and 4 h incubation).

At 4 °C, the ^3H activity of M_o remained equal to M_i until the temperature was raised to 37 °C (Fig. 2a). When both media contained 2 mM iodoacetate, and N_2 in the aeration mixture, net flux of ^3H was not observed, and M_o/M_i remained at unity indefinitely at 37 °C (Fig. 2a). The $M_i \rightarrow M_o$ flux was partially inhibited by 10^{-5} M, and was almost completely blocked by 10^{-4} M PGF$_{2\alpha}$ (Fig. 2b). PGF$_{2\beta}$, a relatively inactive analogue of PGF$_{2\alpha}$ (ref. 12) was found to be more effective than PGF$_{2\alpha}$ itself, yielding essentially complete inhibition of ^3H-PGF$_{2\alpha}$ transport at 10^{-6} M. The unrelated fatty acid, octanoic acid, produced partial inhibition only at a concentration of 10^{-3} M.

To determine how much of the ^3H activity transported across the vagina remained associated with the original PG, both M_o and M_i were removed after 90 or 120 min of incubation and extracted for PGs (ref. 13). Paper chromatography[14] of such extracts showed that only about two-thirds of the ^3H activity of M_o remained associated with PGF$_{2\alpha}$, whereas approximately one-fourth of the ^3H was found with the 15-keto-PGF$_{2\alpha}$ spot. For this reason 10^{-4} .M furosemide was used in all further experiments to inhibit the 15-dehydrogenase activity[15]. In the presence of furosemide the ^3H gradient
Fig. 2 Effects of temperature, metabolic inhibition and high $PGF_{2\alpha}$ concentrations on development of ^3H gradient across isolated rabbit vagina incubated with ^3H-$PGF_{2\alpha}$. *a*, When M_i and M_o had the same initial ^3H-$PGF_{2\alpha}$ activity (total $[PGF_{2\alpha}]$ approximately 10^{-9} M) the $M_i \rightarrow M_o$ flux established a 20-fold M_i/M_o ^3H gradient at 37 °C (●), whereas at 4 °C the M_i/M_o ratio remained at unity until the temperature was raised to 37 °C (O). The ^3H ratio remained at unity indefinitely in anaerobic conditions (at 37 °C) in the presence of 2 mM iodoacetate (△). *b*, The development of M_o/M_i ^3H gradient showed a dose-dependent, reversible inhibition when the $[PGF_{2\alpha}]$ in both M_o and M_i was raised from 10^{-7} (●) to 10^{-5} (O) or 10^{-4} M (△).

was slightly reduced, but the formation of 15-keto-$PGF_{2\alpha}$ was greatly suppressed; thus, in five experiments $89 \pm 2\%$ ^3H activity in M_o and $91 \pm 1\%$ in M_i remained associated with the $PGF_{2\alpha}$ spot on the A1 system[14]. In this condition, a net flux of chromatographically identifiable ^3H-$PGF_{2\alpha}$ against a concentration gradient was observed which resulted in a final, paper chromatographically identifiable, $PGF_{2\alpha}$ M_o/M_i ratio of 7.3 ± 2.5 ($n = 5$). The fact that in the presence of furosemide the bulk of the accumulated ^3H remained associated with $PGF_{2\alpha}$ was also substantiated in four such experiments with a previously described[11] immunoadsorption technique.

To provide further evidence that $PGF_{2\alpha}$ transport does not require a metabolic alteration of the PG molecule, five similar experiments were carried out in which both M_i and M_o contained 10^{-6} M $PGF_{2\alpha}$ and 10^{-4} M furosemide but no ^3H-$PGF_{2\alpha}$. After 2 h incubation, the fluids were removed and the PGs extracted[13]. Immunoassay of these extracts with an anti-$PGF_{2\alpha}$ serum which shows negligible cross-reactivity with 15-keto-$PGF_{2\alpha}$ (ref. 11), showed that the $PGF_{2\alpha}$ content of M_i decreased, whereas that of M_o increased, yielding more than fivefold final M_o/M_i $PGF_{2\alpha}$ gradient. Bioassay of three of these extracts on gerbil colon[16] also showed that the $PGF_{2\alpha}$-like activity of M_o increased whereas that of M_i decreased. As in all these experiments the initial $PGF_{2\alpha}$ concentration of

$M_i = M_o$, these results substantiate the isotope studies indicating that chemically unaltered, biologically active, $PGF_{2\alpha}$ can be transported across a biological membrane against a true concentration gradient.

In three similar experiments, $PGF_{2\alpha}$ was omitted from the initial incubation medium to see whether locally synthesised $PGF_{2\alpha}$ is released into M_o or M_i. After 2 h incubation, a small amount (0.6 ± 0.1 ng; $n = 3$) of $PGF_{2\alpha}$ was found by immunoassay in M_o only. This amount of PG release could not significantly affect the observed PG gradient, but indicates that PGs which are synthesised by the vagina are either released entirely on the serosal side of the barrier or are transported across this barrier preventing their accumulation in the lumen.

The existence of such active PG transport processes could have physiological significance, not only in the case of the vagina[10], blood-ocular fluid[8] and blood-brain [9]barriers, but also with respect to the general distribution and metabolism of these autocoids[7]. PG accumulation against a concentration gradient by the kidney cortex[1], for example, suggests that excretion and/or renal distribution of PGs and/or their metabolites also depends on a carrier-mediated process. PG accumulation by lung tissue[1] and its saturable uptake into isolated perfused rat lung preparation[17] suggests that a carrier-mediated uptake of PGs into the cells may be required for the rapid pulmonary metabolism of PGs.

In conclusion, the energy-dependent, saturable net flux of $PGF_{2\alpha}$ across the isolated rabbit vagina provides direct experimental evidence in support of the concept[1] that PGs can be actively transported by some vertebrate tissues. Concurrent *in vitro* studies on rabbit anterior uvea, choroid plexus and kidney cortex[2,3] indicate that this PG transport mechanism is distinctly different from the iodide transport system, it overlaps with the p-aminohippurate system and may be related to the 'L' component of the iodipamide transport system which was described recently[18]. This PG transport system can be expected to have a fundamental role in the removal of PGs from the extracellular fluids of the eye[8] and the brain[9] and may also have a role in the pulmonary metabolism and renal excretion of PG (ref. 7). The existence of such PG transport processes implies that inhibitors of PG transport may provide an experimental and/or therapeutic tool for the manipulation of the distribution and disposition of PGs.

Differential effects of cyclic AMP on the *in vitro* induction of antibody synthesis

INTRACELLULAR events in lymphocytes following antigenic stimulation still remain largely obscure. It has recently been demonstrated that cyclic AMP is involved during early events of the *in vitro* immune induction, since exogenous application of cyclic AMP can prevent spleen lymphocytes from differentiating into antibody-producing cells[1]. One can assume that this is more than a general effect on cell division processes, since inhibition by cyclic AMP could be demonstrated only during the first 24 h of the immune induction period, whereas cell proliferation starts after 24 h (ref. 2). Since cooperation between T and B cells and proliferation as well as differentiation of these cells are essential features during the early period of the immune response against most antigens[3] it was of interest to study the effect of cyclic AMP on the primary immune response in a T-cell-deficient system such as nude spleen cell cultures. Nude spleen cells can be stimulated to antibody production against sheep red blood cells (SRBC) not only in the presence of allogeneic T cells and antigen[4,5] but also by B cell mitogens, such as lipopolysaccharides (LPS) from various bacteria without a specific antigen[6].

Here, the effect of exogenous cyclic AMP on the T-cell–dependent immune response to SRBC is compared with the T-cell–independent activation by the mitogen LPS and possible events following treatment by cyclic AMP are discussed.

As shown in Table 1, nude spleen cells give rise to only small numbers of antibody-producing cells in the absence of allogeneic thymus cells or a potent mitogen like LPS.

and specific antigen (Table 1), whereas cultures reconstituted with thymus lymphocytes and stimulated by SRBC showed a reduction in the number of plaque-forming cells on day 4.

It was of interest to see whether cyclic AMP affects those events which occur during the cooperation of thymus-derived and bone marrow-derived lymphocytes or rather other processes which are involved in antigen recognition and T cell maturation. Therefore, antigen-activated T cells, as matured T cells, were used to restore the immunological capacity of nude spleen cells in place of allogeneic thymus cells. The effect of cyclic AMP in this culture system was tested and compared with cultures restored with normal allogeneic thymocytes from 4-week-old donors.

From the data of Table 2 we can see that the induction of antibody synthesis is suppressed by cyclic AMP only when normal allogeneic thymus lymphocytes are used for restoration. The addition of cyclic AMP to nude spleen cells restored with antigen-activated T cells did not lead to inhibition of day 4 antibody synthesis against SRBC. No difference in the insusceptibility to cyclic AMP was seen when donors of three different H-2 backgrounds were used as the source of activated T cells. This cooperation across the H_2-barrier may suggest parallels to allogeneic stimulation. In this case, one must conclude that the cyclic AMP independence of antigen-activated T cells in this respect indicates that they have reached a stage in development differing from normal allogeneic T cells.

Differences in the intracellular level of cyclic AMP have been described for different stages in differentiation of mammalian cells[10]. Since it was found that inhibition of the immune induction by cyclic AMP can be effected only during the first 24 h (ref. 1), it was of interest to see whether this intracellular mediator is involved in cooperation events during the early period of the immune induction or rather influences processes

Table 1 Influence of cyclic AMP on the immune response to SRBC in *nu/nu* spleen cells

| Cell cultures | PFC per 10⁶ collected cells | | | | |
	Exp. 1	Exp. 2	Exp. 3	Exp. 4	Exp. 5
nu/nu spleen cells (3 d)	79	—	60	68	55
nu/nu spleen cells (3 d)+SRBC	33	—	72	86	94
nu/nu spleen cells (3 d)+LPS	184	172	310	390	213
nu/nu spleen cells (3 d)+LPS+SRBC	203	142	—	—	—
nu/nu spleen cells (3 d)+LPS+cyclic AMP	164	231	309	295	264
nu/nu spleen cells (4 d)+SRBC	47	63	—	—	—
nu/nu spleen cells (4 d)+SRBC+Thy	303	299	—	—	—
nu/nu spleen cells (4 d)+SRBC+Thy +cyclic AMP	56	54	—	—	—

Cell cultures of spleen cells from *nu/nu* mice with NMRI background were prepared according to the method of Mishell and Dutton[7]. Sheep erythrocytes (SRBC) were used as antigen at a dose of $3 \times 10^6 - 5 \times 10^6$ SRBC per 10^7 cells. Culture dishes reconstituted with thymus lymphocytes contained 1×10^7 nude spleen cells and 5×10^6 thymus cells or 5×10^6 antigen-activated thymus cells, whereas cell cultures supplemented with LPS contained only 1.5×10^7 nude spleen cells. After 3 or 4 d of *in vitro* incubation five culture dishes of one group were pooled. The number of antibody-producing cells was determined with a modified Jerne plaque technique[8]. Cell viability was checked by Trypan blue dye exclusion tests. The number of plaque-forming cells was determined after two different times of incubation *in vitro*. Spleen cells stimulated with LPS were collected on day 3 and cell cultures restored by allogeneic spleen cells were pooled and assayed on day 4 of incubation. Lipopolysaccharides (LPS) from *Salmonella anatum* were used to stimulate nude spleen cell cultures. LPS was extracted by the phenol–water method and purified by ultracentrifugation[9]. It was dissolved in Eagle's medium to a final concentration of 10 μg ml⁻¹. Thy, allogeneic thymus lymphocytes from 4-week-old C57BL; cyclic AMP was used at 10^{-3} mol.

On day 3 the number of plaque-forming cells in cultures to which SRBC had been added did not differ significantly from control cultures without antigen. On the other hand when LPS or allogeneic thymus lymphocytes were added, these nude spleen cell cultures produced increased numbers of plaque-forming cells on day 3 or day 4. There was no significant difference in the 3-d response between cultures supplemented with LPS alone or with both LPS and SRBC, when 10 μg ml⁻¹ LPS was used.

Parallel cultures were treated with 10^{-3} mol cyclic AMP (Boehringer, Mannheim) at the beginning of incubation. This dose was shown to inhibit the immune induction of normal spleen cultures in previous experiments[1]. The application of cyclic AMP has no inhibitory effect on nude spleen cell cultures activated polyclonally with LPS in the absence of thymus cells

dependent on antigenic interaction with T cells.

The data presented here lead to the conclusion that exogenous application of cyclic AMP probably affects those events in the immune induction which are related to T cell function, since LPS-induced differentiation of B cells to antibody-producing cells cannot be disturbed by exogenous cyclic AMP. Also experiments with antigen-activated T cells indicate that the interaction of T and B cells itself is not affected by cyclic AMP, since cooperation can occur in nude cell cultures restored by matured T cells in the presence of cyclic AMP. Because only one of the three culture conditions presented here was influenced by cyclic AMP (namely, nude spleen cells restored by naive thymus lymphocytes) one can conclude that exogenous cyclic AMP disturbs processes which lead to T cell maturation after antigenic stimulation.

Table 2 Influence of cyclic AMP on the immune response to SRBC in *nu/nu* spleen cells* restored with antigen-activated T cells

Cell cultures		PFC per 10^6 collected cells	
	Experiment 1†	Experiment 2‡	Experiment 3§
nu/nu spleen cells + SRBC	5	0	13
nu/nu spleen cells + Thy + SRBC	161	281	157
nu/nu spleen cells + t-act + SRBC	195	489	309
nu/nu spleen cells + Thy + SRBC + cyclic AMP	35	2	2
nu/nu spleen cells + t-act + SRBC + cyclic AMP	408	680	300

For the preparation of antigen-activated T cells 8–12-week-old mice were lethally irradiated with 750 r. They received $1 \times 10^7 - 3 \times 10^7$ thymus lymphocytes intravenously from a syngeneic donor, 4 weeks old. At the same time 3×10^8 SRBC were injected intraperitoneally into each recipient. After 6 d mice were killed, their spleen cells collected and used as antigen-activated T cells (t-act)

§ BALB/c mice ⎭

The differential effect of cyclic AMP on nude spleen cell cultures supplemented either with allogeneic thymus cells or antigen-activated T cells corresponds to the differential effect of cyclic AMP in normal spleen cultures, when the immune response is prevented only during a critical time during immune induction[1]. Therefore it seems reasonable to relate the action of this cyclic nucleotide in normal cells to early processes in thymus lymphocytes induced by antigen. Although Watson *et al.* found that the immune response is inhibited when B cells are treated with cyclic AMP before antigen presentation[12], more recent results of Watson[13] and others (J. Anderson, F. Melchers, and S. Bauminger, personal communication) demonstrate that the intracellular level of cyclic AMP in nude spleen cells is not changed significantly after stimulation by LPS, whereas the intracellular level of cyclic GMP rises dramatically.

Our results are also related to other reports on cyclic AMP binding sites on the cell surface of thymus lymphocytes and intracellular measurements which show changed levels of cyclic AMP in thymus lymphocytes[11].

Treatment of nude spleen cells with theophylline results in inhibition of antibody production after LPS stimulation (R. Bösing-Schneider, unpublished). This effect is not understood, because the intracellular level of cyclic AMP in these cells is not changed after stimulation by LPS (ref. 13). Since cyclic GMP seems to have an important role in these cells[13] one can question if the cyclic GMP phosphodiesterase is affected by theophylline.

Our experiments have shown that exogenous cyclic AMP had an inhibitory influence only in cell cultures restored by allogeneic thymocytes and stimulated by antigen, whereas in cultures activated polyclonally[6] with LPS, in the absence of thymus cells and antigen, no inhibition effect was detectable. Further experiments with antigen-activated T cells lead to the conclusion that treatment of cell cultures with cyclic AMP may affect only those antigen dependent processes which lead to T cell maturation.

Evidence for the induction of two antibodies with identical combining sites in outbred animals

THE mechanism by which the immune system produces an apparently limitless array of antibodies in response to a variety of antigenic stimuli remains an unresolved biological question. Primary structural analysis has shown that immunoglobulin heavy (H) and light (L) chains have both variable (V) and constant (C) regions of amino acid sequence. Within the V_H and V_L region sequences there are areas of hypervariability which are thought to be associated with the antibody combining site. It is the amino acid substitutions within certain of these hypervariable areas that result in the multiplicity of antibody specificities (sites) expressed in nature. It seems clear that separate genes code for the V and C regions of H and L chains and that integration of V- and C-region genes occurs at the DNA level[1]. One can account for antibody isotypic diversity by postulating a limited number of C-region genes which are transmitted from generation to generation in the germ line. The difficulty arises in the attempt to account for the apparent large numbers of V-region genes required to explain antibody combining site diversity. V-gene counting has been accomplished by RNA–DNA hybridisation[2-4]. Evidence from these studies has not definitely demonstrated whether the capacity to generate large numbers of combining sites exclusively arises by either the inheritance of a complete set of V_H and V_L genes in the germ line or by somatic mutation. The repeated occurrence of V-gene products has, however, been indicated by sequence analysis of myeloma proteins[5-7], isoelectric focusing[8-10], and idiotypic analysis[11-13].

It thus seems that an abundance of evidence favours repeated V-region genes in inbred systems and supports the germ line hypothesis[14-16]. It now becomes important to map particular V regions and to show whether they are stably retained in an outbred population. Support for the stability of V-region genes in outbred systems comes from the discovery of apparently identical phosphorylcholine combining sites in different inbred mouse strains[13] as well as highly similar V-region sequences (differing by only 8 residues, 3 being located in the hypervariable regions) in two human IgM myeloma heavy chains obtained from genetically distinct individuals[17]. To gain additional insight into V-region gene transmission and stability in a randomly outbred species we are currently mapping V regions from antibodies directed against the DNP determinant. Our studies have taken advantage of the antigen (DNP)$_2$-gramicidin S,

which reproducibly elicits antibodies of limited structural heterogeneity (refs 18, 19), thereby maximising recognition of particular V regions. Here we examine evidence suggesting that antibodies with identical combining sites have been elicited in two outbred rabbits and provide additional evidence that the genetic information necessary to account for V-region (combining site) diversity is present and stably transmitted in the germ line.

A detailed analysis of the immune response to $(DNP)_2$-gramicidin S has been reported previously[18,19]. These studies showed that a number of rabbits producing anti-DNP antibodies possessed monoclonal characteristics[19]. Initial assessment of monoclonality was based on: (1) the spectral similarities of these antibodies to myeloma proteins and (2) the lack of binding heterogeneity as reflected in unitary heterogeneity indices. Further evidence for homogeneity was obtained from chain reassociation studies in which these purified antibodies regained their original binding constants after reduction, alkylation and exposure to dissociating conditions[19].

Figure 1a shows the isolectric spectra of six rabbits possessing monoclonal spectrotypes. It is evident that the monoclonal responses were not confined to rabbits possessing identical serum allotypes nor did individual antibodies necessarily possess identical spectrotypes. Two antibodies

Fig. 1 Serum aliquots (100 μl) or purified antibodies (200–400 μg) were focused in 5% thin-layer polyacrylamide gels containing pH 3.5–10 or 6–8 ampholine carrier ampholytes (LKB). Anti-DNP antibodies were seen after interaction with ^{131}I HDL, by contact autoradiography[18]. a, Isoelectric analysis of serum from rabbit 13 (track 1, allotype a13, b44), rabbit 22 (track 2, allotype a12, b44), rabbit 71 (track 3, allotype a13, b44), rabbit 126 (track 4, allotype a33, b44), rabbit 127 (track 5, allotype a33, b44) and rabbit 129 (track 6, allotype a13, b44) on pH 3.5–10 ampholyte gels. These characteristic monoclonal anti-DNP antibody spectra were perpetuated with antigenic stimulation until the death of each rabbit. b, Isoelectric analysis of antibodies from rabbits 13 (tracks 5 and 6; 6 and 18 months after initial immunisation) and 22 (1, 2 and 3; 6, 12 and 24 months after initial immunisation) on a pH 6–8 ampholyte gel. Track 4 was obtained by mixing equal quantities of purified antibodies from each rabbit.
Table 1 Association constants of anti-DNP antibodies before and after recombination*

(track 1, rabbit 13, and track 2, rabbit 22) which seemed to display similar spectrotypes, were analysed further on isoelectric gels containing expanded range ampholytes. Figure 1b shows a detailed analysis of rabbits 22 (tracks 1, 2, 3,) and 13 (tracks 5 and 6). Track 4 was obtained by mixing equal quantities of these two antibodies and shows that the spectra are not, in fact, identical. In view of our subsequent findings, these slight spectral differences may result from biochemical modifications outside the combining site and perhaps outside the V region. In spite of spectral differences, both antibodies possess identical association constants (Table 1) which suggests possible combining site similarities.

To test this possibility we undertook a series of chain recombination experiments. Chain recombination has been used previously to assess the heterogeneity of mouse[20] and rabbit[21] antibodies. Our preliminary recombination studies with rabbit 13 and 22 antibodies had shown that complete regain of binding activity could be obtained when chains from homologous antibodies were allowed to reassociate Table 1)[19], a behaviour characteristic of monoclonal antibodies[20,21]. We used cross chain recombination studies to study the relationship of the combining site structure of these two antibodies. Fig. 2 outlines the experimental protocols used in this analysis. The quantities of monoclonal antibodies precluded the exclusive use of separated chains in every experiment, so initially it was important to compare the two recombination protocols. Table 1 summarises the data from these experiments. The K_0 values on the left were obtained before reduction and alkylation, the values on the right after reassociation following the indicated protocol. Mouse MOPC-315 IgA, a myeloma protein with reactivity for DNP, completely regained its original K_0, whereas a heterogeneous population of rabbit anti-DNP antibodies showed a drop of 4 log units. These data confirmed that the recombination system can distinguish monoclonal and heterogeneous antibody populations and justified the use of either recombination protocol. The data on the two monoclonal antibodies show that recombinant 7S molecules prepared from either H (13) and L (22) or H (22) and L (13) displayed K_0 values identical to recombinants prepared with homologous H and L chains. Control experiments showed that H (13) or H (22) did not possess K_0 values of parent molecules, nor did recombinants prepared using these H chains and L chains from other anti-

Fig. 2 Alternative protocols used in the recombination studies. Antibodies were purified by affinity chromatography on DNP–Sepharose immunoadsorbent columns[19] and aggregates removed by chromatography & (Sephadex G-150). 7S antibodies were mildly reduced for 2 h in 0.1 M 2-mercaptoethanol in 0.2 M Tris (pH 8.0) under N_2 at 25 °C followed by alkylation for 30 min with a 10% molar excess of iodoacetamide (in certain cases 1-^{14}C iodoacetamide was used to label the H and L chains). The dissociation of the mildly reduced and alkylated chains was either accomplished by dialysis against 1 M propionic acid or by physical separation on Sephadex G-100 equilibrated in the same solvent. Separated chains (mixed in a ratio of 1.2 mol L chain per mol H chain) or dissociated chains were allowed to reassociate by sequential dialysis against 500-fold excess amounts of 0.05 M propionic acid (once), H_2O (twice) and borate buffered saline (pH 8.3) (twice). Recombinant 7S molecules were recovered from a calibrated Sephadex G-150 column[19]. Association constants (K_0) were determined by fluorescence quenching at 4 °C (ref. 19).Each K_0 value represents the average of at least three titrations.

DNP antibodies (Table 1 and unpublished observations). Jaton (Basel Institute for Immunology) has carried out recombination studies[22] on homogeneous anti-pneumococcal type III antibodies which have been sequenced[23,29]. Recombinant molecules prepared with H chains and heterologous L chains differing by as few as 6 hypervariable residues (total of 8 substitutions within the amino terminal 139 residues) do not regain appreciable binding activity, whereas recombinants prepared with homologous H and L chains do[22]. In fact, to date, Jaton (personal communication) and others[25] have only been able to achieve the binding activity of the parent molecule when H and L chains come from the same parent molecule. Our argument for combining site identity would, of course, be strengthened by amino acid sequence data. Jaton's findings demonstrate, however, that the chain recombination technique is a powerful probe of combining site fine structure[22]. The interpretation of our data in the light of these findings leads to the suggestion that rabbits 13 and 22 most probably possess identical combining sites.

The probability of two such antibodies arising purely by somatic mutations and being expressed in 2 out of as few as 100 rabbits seems low. Confidence in the random breeding of these two rabbits comes from the knowledge that each was immunised in a different country. The stability of these responses is illustrated by the fact that they were potentiated up to 1.5 (rabbit 13) to 2 (rabbit 22) years, without variation. When stimulation was discontinued for 6 months (rabbit 13), the response disappeared. Restimulation induced identical monoclonal antibody. Recent studies have suggested that two or more genes may code for heavy chain V regions, one specifying framework residues including the group a allotype, another specifying the idiotype[26,27]. The two rabbits studied in detail here (rabbits 13 and 22) were heterozygous for the a allotype, both sharing the

a1 allotype. Finding the same allotype on antibodies with identical combining sites would suggest repetition of the entire V region, although sequence data would be needed to confirm such a speculation. It remains possible that a given combining site is not confined to a particular allotype and present investigations are directed at determining if identical sites may be present on antibodies of different allotypes.

The apparent ability to induce identical combining sites in outbred members of the same species lends strong additional support to the notion that a particular V-region gene may persist and be transmitted stably in the germ line while apparently undergoing minimal mutations in regions not affecting the combining site.

We thank Dr R. Mage for her generosity in carrying out the allotype determinations, Dr J.-C. Jaton for making his data available before publication, and Dr A. Williamson for critical comments on the manuscript.

Detection of reverse transcriptase in human breast tumours with poly(Cm)·oligo(dG)

PARTICLES having the density of type-C RNA tumour viruses, possessing reverse transcriptase (RNA-directed DNA polymerase) activity, and containing high molecular weight RNA that shares a portion of its base sequences with the RNA of murine RNA tumour viruses, have been reported to be present in several types of human malignant tissues, but not in their normal counterparts (review, see ref. 1). The endogenous RNA→DNA synthetic capabilities of these particles were used in a simultaneous detection test[2,3] to determine these parameters. Because of their

similarity and relatedness to animal oncornaviruses, these particles are considered to be possible aetiological agents of human cancer[2].

To establish more firmly the presence of particles containing reverse transcriptase activity in human tumours, and to delineate the difficulties involved in the use of an exogenous synthetic probe to detect the enzyme in crude extracts, we have examined a number of human tissues for reverse transcriptase activity using poly(2'-o-methylcytidylate)·oligodeoxyguanylate [poly(Cm)·oligo(dG)] as template primer. Poly(Cm)·oligo(dG) is an effective template primer for every reverse transcriptase so far tested, including the enzymes from RNA tumour viruses of avian, murine, feline, and primate origin[4] (G.F.G., unpublished). Neither bacterial DNA polymerase I nor any of the eukaryotic DNA polymerases tested, including the three major DNA polymerase species from mouse 3T6 or human KB and HeLa cells[1,4,5], can copy poly(Cm)·oligo(dG). In particular, highly purified DNA polymerase γ from HeLa cells, an enzyme that resembles viral reverse transcriptase in its ability to copy poly(C)·oligo(dG)[6], does not copy poly(Cm)·oligo(dG)[5]. Poly(Cm)·oligo(dG) is therefore a specific template primer for viral reverse transcriptase. Using this specific probe, we have detected reverse transcriptase activity in particulate material isolated from the postmitochondrial cytoplasm of approximately 50% of the

Fig. 1 Identification of the density of reverse transcriptase and phosphatase activity in a postmitochondrial extract of human mammary tumour by sucrose gradient centrifugation. A P-90 pellet from 13 g of human mammary tumour was prepared and fractionated on a 15–65% sucrose gradient as described in the legend to Table 1. Individual fractions within nine density regions were pooled, particulate material pelleted, and the pellets suspended as in Table 1. Samples (10 μl) from each suspension were diluted and assayed for dGTP phosphatase (open bars) as follows. The phosphatase sample was added to a reaction mixture (50 μl) containing 20 mM Tris-HCl (pH 7.8), 0.2 mM MnCl$_2$, and 3.7 μM ³H-dGTP (2,900 c.p.m. pmol^{-1}). After 30 min at 37 °C, the reaction was terminated by heating at 100 °C for 2 min. The amount of ³H-dGTP remaining in the reaction mixture was then determined by using it as a substrate for excess DNA polymerase. A solution (50 μl) was added to the heated mixture containing 10 mM Tris-HCl (pH 7.8), 10 mM dithiothreitol, 5 mM MgCl$_2$, 0.1 mM each dCTP, dATP, and dTTP, 300 μg ml^{-1} activated calf thymus DNA, and 1.4 units of *Micrococcus luteus* DNA polymerase (P-L Biochemicals). After a 60 min incubation at 37 °C, the amount of labelled DNA product formed was determined on Whatman DE-81 filters[4]. The total remaining suspensions (990 μl) from density regions III (1.185–1.170 g cm^{-3}), IV (1.165–1.150 g cm^{-3}), V (1.145–1.130 g cm^{-3}), and VI (1.125–1.115 g cm^{-3}), were lysed, fractionated on separate phosphocellulose columns, and assayed for reverse transcriptase (solid bars) and transferase as in the legend to Table 1. Density regions I and II were directly assayed for reverse transcriptase activity after lysis without fractionation on phosphocellulose. No activity was observed in I and II. No transferase activity was observed in any density region.

human mammary tumours we have examined, but not in the cytoplasm of non-malignant breast tissue. It was necessary to remove interfering deoxyribonucleotide phosphatase activity present in human tissue extracts by phosphocellulose chromatography before reverse transcriptase activity could be detected.

We have taken the approach of isolating particulate material with a density between 1.15 and 1.20 g cm^{-3}, a density range characteristic of RNA tumour viruses, from the postmitochondrial cytoplasm of human tissue, and after treating the particulate material with non-ionic detergent, assaying for DNA polymerase activity with poly(Cm)·oligo (dG) (for experimental details, see the legend to Table 1). This approach minimises intereference in the assay by cellular enzymes, such as nucleases and other polymerases[2,3]. It was discovered, however, that all tissue extracts examined, regardless of the human organ of origin, contained an inhibitor of poly(Cm)·oligo(dG)-directed poly(dG) synthesis, deoxyribonucleotide phosphatase (Fig. 1). By paper chromatographic analysis, the phosphatase activity was found to hydrolyse ³H-dGTP or ³H-TTP through mono and diphosphate intermediates to the deoxyribonucleoside level (G.F.G., unpublished). To facilitate removal of phosphatase from the cytoplasmic particulate fraction of tissues, we developed a rapid and convenient assay for dGTP phosphatase that uses residual ³H-dGTP in an activated calf thymus DNA-directed polymerising reaction catalysed by excess DNA polymerase (G.F.G. and P.M.L., in preparation). Details are described in the legend to Fig. 1.

Using this assay, we found that the postmitochondrial, cytoplasmic particulate fraction from 10 g of human liver, spleen, kidney, or breast that banded in the 1.15 to 1.20 g cm^{-3} density region of 15–65% sucrose gradients, contained sufficient phosphatase to hydrolyse from 0.8 to 1.2 μmol of ³H-dGTP in 30 min. To carry out a poly(Cm)·oligo(dG)-directed assay in standard conditions without inhibition by phosphatase, the level of the enzyme in particulate cytoplasmic extracts would have to be reduced by 500 to 1,000-fold. The only technique we have found which removes enough phosphatase activity is phosphocellulose chromatography. In the presence of 0.1 M NaCl, phosphatase activity is not adsorbed by phosphocellulose, whereas reverse transcriptase from particles treated with Nonidet P-40 (NP-40) is bound and can be eluted with 0.25 M NaCl. By seeding human tissues (liver, kidney, spleen, breast) with various concentrations of RNA tumour viruses such as murine sarcoma-leukaemia or RD114 virus and using the procedure described in the legend to Table 1 to isolate reverse transcriptase, we have found in general that from 14 to 38% of the reverse transcriptase activity responding to poly(Cm)·oligo(dG) present in seeded virus is recovered in a volume of 2 ml from phosphocellulose columns.

Table 1 summarises our results with 19 human breast carcinomas and 9 non-malignant control tissues. Phosphocellulose eluates were assayed for DNA polymerase activity with poly(Cm)·oligo(dG), for terminal deoxyribonucleotidyl transferase activity with oligo(dG)[7], and for background radioactivity without template or primer. Backgrounds averaging 235 ± 72 c.p.m. were subtracted in all cases. No significant transferase activity was detected in any of the tissue samples examined. The average incorporation observed with the non-malignant control tissues with poly(Cm)·oligo(dG) was 59 c.p.m. In contrast, the average with the malignant tissues was 837 c.p.m. On the basis of the magnitude and variability of the background trapping of radioactivity, there was a 90% probability that all tissues which gave 200 c.p.m. or more incorporation above background were positive for activity. On this evaluation, 53% of the malignant samples were positive for reverse transcriptase by the poly(Cm)·oligo(dG) assay and all the control samples were negative. It should be pointed out that 5 of

the 9 malignant tissues which were negative weighed less than 5 g, which may have had a direct bearing on the low level of enzyme activity observed.

In addition to activity with poly(Cm)·oligo(dG), we have also examined phosphocellulose eluates prepared from a number of human carcinomas and non-malignant tissues for DNA polymerase activity with poly(C)·oligo(dG) and poly(A)·oligo(dT) in the presence of $MnCl_2$. Tissues negative for activity with poly(Cm)·oligo(dG) were also negative with poly(C)·oligo(dG), and positive responses to these template primers were comparable in magnitude. In contrast, there was not always a correlation between response to poly(Cm)·oligo(dG) and to poly(A)·oligo(dT). For example, in both normal and malignant breast tissue extracts in which there was no response to poly(Cm)·oligo(dG), we sometimes observed no activity with poly(A) oligo(dT) or activity which catalysed the incorporation of from 700 to 20,000 c.p.m. of ³H-TTP in response to poly(A)·oligo(dT). This activity probably represents variable contamination by DNA polymerase γ (ref. 6) of tissue extracts prepared by

Frozen human breast tissue, 2–14g, was finely minced and disrupted with a Silverson homogeniser at 4 °C in 3 volumes of 0.01 M Tris-HCl (pH 8.3) +0.15 M NaCl+0.002 M EDTA (TNE)³ The suspension was centrifuged at 4,000g for 20 min at 4 °C and the pellet washed with 1 volume of TNE and recentrifuged The supernatants were combined and centrifuged again at 10,000g for 10 min. The pellet was washed with TNE and recentrifuged The 10,000g supernatants were combined and treated with trypsin (1 mg ml⁻¹ for 30 min at 37 °C) which was inactivated with Lima bean trypsin inhibitor (0.4 mg ml⁻¹). The treated supernatant was layered on a 12-ml column of 20% glycerol in TNE and spun at 90,000g for 1 h at 4 °C in an SW27 rotor. The resulting pellet (P-90) was suspended in 4 ml of TNE and layered on a 30 ml 15–65% (w/v) sucrose gradient in TNE and centrifuged at 90,000g for 12–14 h in an SW27 rotor Fractions (40 to 50) were collected from below, and those in the density range of 1.145 to 1.20 g cm⁻³ were combined, diluted with TNE to bring the sucrose concentration below 10%, and centrifuged at 150,000g for 1 h in a Ti60 rotor. The resulting pellet was suspended in 1 ml of 0.02 M Tris-HCl (pH 7.8)+0 001 M dithiothreitol+0 1 mM EDTA+ 10% glycerol (Buffer A), NaCl and NP-40 were added to 0.1 M and 2%, and the lysate incubated at 0 °C for 15 min. The lysate was applied to a 0.9×3 cm phosphocellulose (P-11, Whatman) column equilibrated in Buffer A +0.2% NP-40. The column was washed with 20 ml of Buffer A+0.2% NP-40+0.1 M NaCl, and eluted with 10 ml of Buffer A+0.2% NP-40+0.8 M NaCl. Fractions of 1 ml were collected. A sample (250 µl) of the first fraction from the phosphocellulose column containing an increased concentration of NaCl (usually 0.15 to 0.2 M) was incubated for 1 h at 37 °C in a reaction mixture (500 µl) containing 20 mM Tris-HCl (pH 8.0), 1 mM dithiothreitol, 0.2 mM MnCl₂, 30 µM poly(Cm), 15 µM (dG)₁₂₋₁₈, and 2–4 µM ³H-dGTP (2 3–2.7×10⁴ c.p.m. pmol⁻¹). Additional samples were assayed (i) in the absence of poly(Cm) and (ii) in the absence of both poly (Cm) and (dG)₁₂₋₁₈. The amount of trichloracetic acid insoluble radioactivity in the reaction mixture was determined by collection of the product on nitrocellulose filters after washing by repeated precipitation and dissolution with perchloric acid and NaOH⁴.
* A repeat 1-h incubation was carried out.
† A repeat 2-h incubation was carried out.
‡ Not determined.
Fig. 2 Identification of the density of reverse transcriptase and phosphatase activity in an extract of human mammary tumour treated with nonionic detergent. A P-90 pellet from 50 g of human mammary tumour was prepared and fractionated on five, 15–65% sucrose gradients and particulate material with a density of 1.15 to 1.20 g cm⁻³ was pooled and pelleted in a Ti60 rotor as described in the legend to Table 1. The pelleted material was suspended in 600 µl of 0.1 M Tris-HCl (pH 8.3), and dithiothreitol and Sterox-SL were added to final concentrations of 100 mM and 1%, respectively. The lysate was layered on a 11.5-ml gradient of 25–85% (w/v) in TNE and was centrifuged at 180,000 g for 14 h in a SW41 rotor. The gradient was fractionated into nine density fractions, and the fractions were diluted with TNE to bring the sucrose concentration below 10% and were centrifuged at 150,000g for 1 h in a Ti60 rotor. The resulting pellets were suspended in 200 µl of 0.01 M Tris-HCl, 0.01 M dithiothreitol, and 0.5% NP-40. Samples (10 µl) from each lysate were assayed for phosphatase (solid bars) as described in the legend to Fig. 1. Samples (50 µl) were directly assayed for reverse transcriptase activity (open bars) and transferase activity in 100 µl reaction mixtures as in Table 1. The average background incorporation was 225 c.p.m., and no appreciable transferase activity was observed in any fraction.

our procedures. The relative template efficiencies of poly(C)·oligo(dG), poly(A)·oligo(dT) and poly(Cm)·oligo(dG) with MnCl₂ for a purified mammalian RNA tumour virus (murine leukaemia virus) reverse transcriptase are 1.0, 0.7 and 0.2, respectively (refs 4 and 5 and G.F.G., unpublished).

To demonstrate that the DNA polymerase activity responding to poly(Cm)·oligo(dG) observed in human mammary tumours, but not in non-malignant breast tissue, is derived from RNA tumour virus-like particles, the DNA polymerase-containing material was further characterised with respect to two properties. First, the exact density of the particulate, poly(Cm)·oligo(dG)-directed DNA polymerase activity from a human breast tumour was determined by sucrose gradient equilibrium centrifugation. Figure 1 shows that the majority of material which contained DNA polymerase activity responding to poly(Cm)·oligo(dG) banded between 1.15 and 1.165 g cm⁻³, a density range characteristic of RNA tumour viruses. Figure 1 also illustrates the large amount of phosphatase activity present in the cytoplasm of human breast tissue which peaks at a density of 1.11 to 1.13 g cm⁻³ in sucrose gradients, but overlaps into the the 1.16 g cm⁻³ region.

Second, nucleoids or cores that contain the reverse transcriptase and possess a density of 1.26–1.27 g cm⁻³ can be generated from RNA tumour viruses by treatment of virions with non-ionic detergent[8]. By treatment with 1% Sterox-SL of the particulate material with a density of 1.15–1.20 g cm⁻³ from the postmitochondrial supernatant of 50 g of human mammary tumour, we were able to isolate reverse transcriptase activity responding to poly(Cm)·oligo(dG) that banded in the density range of 1.21 to 1.30 g cm⁻³ (peaked at 1.265 g cm⁻³) on a 25–85% (w/v) sucrose gradient (see Fig. 2). This material probably repre-

sents cores of breast particles containing reverse transcriptase. DNA polymerase activity at the top of the gradient represents solubilised enzyme partially dissociated from particulate material and not contained within an intact core[8,9]. Also demonstrated in Fig. 2 is the fact that most of the phosphatase contamination of the particle preparation (seen in Fig. 1) is eliminated by detergent treatment and subsequent equilibrium and velocity centrifugation, so that phosphocellulose chromatography before assay of DNA polymerase activity was not necessary.

The results reported here demonstrate that some human breast tumours, but not non-malignant breast tissues, contain particulate, poly(Cm)·oligo(dG)-directed DNA polymerase activity present in a structure possessing the density of an RNA tumour virus. Some of the DNA polymerase activity can be made to band at a density characteristic of virus nucleoids by treatment with a neutral detergent In the light of these findings and the specificity of poly(Cm)·oligo(dG) for viral reverse transcriptase in other systems[1,4,5], it seems reasonable to conclude that we are detecting the enzyme in human breast tumours. It is clear from our experiment that the problem of phosphatase contamination is serious and must be overcome for successful demonstration of the enzyme. The synthetic probe provides an alternative to simultaneous detection[3] for the identification of RNA-directed DNA polymerase activity in human tissues, and investigations are under way using poly(Cm)·oligo(dG) to search for the enzyme in other human tumours and differentiating tissues.

The significance of particle bound RNA-directed DNA polymerase in human breast cancers is not known. It is conceivable that these particles represent infectious, exogenous aetiological agents of the disease. An alternative hypothesis is that the cancer cell represents a partially differentiated cell that is blocked in further development and continues to express information specific for its developmental state, which could include RNA-directed DNA polymerase associated with specific RNA molecules[1]. The retention of this information, normal for a specific state of development, would then be associated with the specific cancer cell type, and its expression could even be responsible for the malignant state of the cell.

Polyadenylic acid sequences in *E. coli* messenger RNA

It is commonly assumed that the messenger RNA (mRNA) of prokaryotes lacks the poly(A) sequences which characterise the 3′ terminus of most mRNA of eukaryotes. A report of the absence of poly(A) sequences from both pulse labelled and stable RNA of *Escherichia coli*[1] is often cited as evidence for such a distinction. This apparent difference has generated speculations ranging from the role of poly(A) sequences in regulating the longevity of eukaryotic mRNA molecules[1], to the evolutionary origin of mitochondria[2] in which poly(A) sequences have been found in a messenger-like RNA[2-5]. Such speculations prompted us to re-examine evidence for AMP-rich sequences in *E. coli* reported[6] before poly(A) sequences were known to be attached to mRNA in animal cells[7-9]. We have found that RNA molecules can be isolated from *E. coli* with the techniques developed for the isolation of poly(A) containing RNA of eukaryotes[10] which have properties of mRNA and contain poly(A) sequence at their 3′ terminus.

Table 1 presents evidence for the presence of poly(A)-containing RNA in *E. coli*. A fraction of total RNA labelled either with a pulse of ³H-adenosine or for 10 min with ³²PO₄ could be bound to oligo(dT) cellulose. Seventy to eighty-five per cent of this RNA could be rebound to oligo(dT) cellulose, showing that nonspecific binding of RNA accounted for little of the RNA bound initially. These data compare favourably with those obtained from HeLa cell mRNA using the same conditions (Table 1, experiment 5). The poly(A) sequences released from these RNA fractions by treatment with ribonucleases and DNase contained about 15% of the total incorporated label showing that the fraction binding to oligo(dT) cellulose (Table 1) was neither free poly(A) nor merely an AMP-rich fragment

In the ³H-adenosine pulse labelling experiments, the fraction of the total RNA binding to oligo(dT) cellulose was considerably lower than would be expected if all mRNA species contained a poly(A) sequence of at least 20 nucleotides which is close to the lower limit of poly(A) length that can be isolated in our conditions (unpublished). In view of the rapid turnover of *E. coli* mRNA and the relatively small size of the poly(A) sequence, variations in the fraction of RNA binding to oligo(dT) may be expected. The average size of poly(A)-containing RNA, as well as the size of the poly(A) sequence itself, tended to vary in different experiments (data not shown). The discrepancy in the fraction of poly(A)-containing RNA binding to oligo(dT) cellulose in the two ³²P-labelling experiments could be explained by the fact that the average lengths of the RNA and its poly(A) sequence in experiment 6 were considerably shorter than in experiment 7 (data not shown).

A rapid turnover of either the poly(A)-containing RNA or the poly(A) sequence is suggested because the poly(A)-containing RNA binding to oligo(dT) cellulose comprised much less of the total stable RNA species of *E. coli* (experiment 4, Table 1).

Figure 1 shows the electrophoretic mobilities of both bound and unbound RNAs in denaturing polyacrylamide gels (98% formamide), as well as the poly(A) sequence released by RNases from the bound RNAs. As Fig. 1*b* shows, bound RNA migrated more slowly than tRNA and almost no label migrated with a mobility similar to the poly-(A) derived from this same RNA fraction. Clearly the failure to find label in gel fractions migrating in the region of the poly(A) sequences means that poly(A) must be covalently attached, since this RNA had been denatured by heating at 60 °C in a large excess of unlabelled poly(A) before its application to denaturing gels. Any measurable labelled poly(A) hybridised to RNA should have been lost through competition with the excess of unlabelled poly(A) present during denaturation.

Figure 1*b* shows that poly(A)-containing RNAs are poly-

Table 1 Isolation of poly(A)-containing RNA from *E. coli*

RNase T₁+RNase A	46,000	2.1	95.6	1.6	0.7	92

Poly(A) was isolated from a poly(A)-containing RNA labelled for 10 min with $^{32}PO_4$. Nuclease treatment as described in Table 1 except that in one case RNase A was omitted. After gel electrophoresis, fractions were pooled as shown in Fig. 2, and the poly(A) recovered was hydrolysed with 0.3 N KOH for 18 h at 37 °C. Nucleotide composition was determined by the method of Osawa *et al.*[19].

disperse, migrating from 4S to 20S. When the logarithm of molecular weight of HeLa 28S, 18S and tRNA which were coelectrophoresed with this RNA and the poly(A), were plotted against their relative mobilities[18], molecular weights of 130,000 and 13,000 were calculated for peak positions of poly(A)-containing RNA and poly(A) respectively, which agreed well with the 11.5% poly(A) content of this RNA.

The polydispersity and greater concentration of these poly(A)-containing RNAs in pulse-labelled RNA suggest

Fig. 1 Electrophoresis of poly(A)-containing RNA and poly(A) in polyacrylamide gels in formamide. Aliquots of RNA and poly(A) from experiment 7 in Table 1 were mixed with 20 μg of non-radioactive poly(A) and ³H-labelled HeLa cell RNA in 98% formamide containing 20 mM NaCl and 10 mM Tris HCl, *p*H 7.6, and heated for 1 min at 60 °C. After cooling at 0 °C, bromophenol blue and sucrose were added. Electrophoresis in 19 cm of 4.2% polyacrylamide gels in formamide was carried out for 5 h at 11 V cm⁻¹ as described[18]. Fractions collected with a Maizel fractionator were counted in a toluene scintillation fluid containing Triton X-100. *a*, Unbound RNA (37,000 cm); *b*, bound RNA (46,000 c.p.m., ○) and poly(A) (5,300 c.p.m., ●) electrophoresed on parallel gels are plotted on the same figure. |—| dye marker; ↓ HeLa 28S RNA (molecular weight 1.9×10^6), 18S RNA (0.71×10^6) and 4S RNA (27,000).

they are species of mRNA although evidence for their translation has not been sought. A relatively small fraction of the total label in the unbound RNA was in ribosomal RNA in these conditions (Fig. 1*a*), showing that labelled mRNA comprised a significant amount of total RNA If at least
Fig. 2 Electrophoresis of the poly(A) sequence in 10% polyacrylamide gel in formamide. An aliquot of the poly(A) of experiment 7 (Table 1) was coelectrophoresed with HeLa ³H-labelled RNA in a 12 cm, 10% polyacrylamide gel in formamide (98%) at 14 V cm⁻¹ for 4.5 h. After fractionating as in Fig. 1, ^{32}P was measured by Cerenkov radiation. Aliquots of fractions 8–20 were counted as in Fig. 1 to locate ³H-labelled 5S and 4S RNA.

50% of total radioactivity was in mRNA, then poly(A)-containing RNA comprised less than 3% of mRNA.

Figure 2 shows an electrophoretogram of ^{32}P-poly(A) isolated after RNase T₁ treatment of the RNA. Poly (A) again migrated faster than the 4S and 5S RNA of HeLa cells. From its electrophoretic mobility in formamide gel, this ^{32}P-labelled poly(A) sequence was estimated to contain about 45 nucleotides.

The GMP content (Table 2) of the poly(A) sequence from RNase T₁ digested RNA shown in Fig. 2 indicates that poly(A) is near the 3' end of RNA, since there is far less than one GMP residue for a sequence of about 40 nucleotides. When hydrolysed with RNase T₁ and RNase A, the RNA yielded a poly(A) lacking UMP residues. The CMP and GMP residues found in this poly(A) could either be contaminants or nucleotides at the 3' end of the sequence. The first possibility is likely for CMP since the alkaline hydrolysis of poly(A) always produces about 1% of a component which comigrates with CMP during electrophoresis[21].

Absence of these nucleotides from the 3′ end of poly(A) was, however, shown more directly when a RNase T_1 and RNase A digest of RNA from cells labelled with ^{3}H-adenosine released 6,000 c.p.m. in the poly(A) sequence of which 5,200 were recovered in AMP and 210 in adenosine. The average chain length of 25 calculated from these values was compatible with, although not identical to, the length of the ^{32}P-labelled poly(A) estimated by gel electrophoresis in Fig. 2. These data along with those of Table 2 show the poly(A) sequence of *E. coli* to be at the 3′ end of the RNA as is the case for the mRNA of eukaryotic cells[17,20,21].

The detection in *E. coli* of poly(A) sequences covalently bound at the 3′ ends of RNAs with characteristics of mRNA should eliminate speculation on roles for poly(A) sequences which define a function of eukaryotes not shared by prokaryotes, such as transport of mRNA from the nucleus. For the same reason, the presence of poly(A) sequences in mitochondria can no longer be used as evidence against the prokaryotic origin of mitochondria.

The concentration of poly(A) sequences in both pulse and fully labelled *E coli* shows that, in contrast to animal cells and yeast, probably no more than 3% of mRNA molecules contain a poly(A) sequence long enough to bind to oligo(dT) cellulose. This difference is perhaps not surprising since the coupling of translation with transcription in prokaryotes may not allow the accumulation of many mRNAs with completed 3′ termini. The low levels could also account for the failure of Perry *et al.*[1] to detect poly(A) sequences in *E. coli* mRNA, since they are close to the noise level reported for their experiments In addition, the Millipore filter techniques they used would not have bound poly(A) sequences as short as those found here[22,23].

Although only a few mRNA species of *E. coli* have poly-(A) at the 3′ terminus, many mRNAs may have oligo(A) sequences at the 3′ terminus which are too short to bind such RNA to oligo(dT) cellulose. Such adenylated 3′-termini have been found on the mRNAs synthesised *in vivo* after T_7 (ref. 24), as well as Φ80 phage[25] infection of *E. coli*. In both cases a variability in the yield of 3′ adenylated mature mRNA species and the length of the oligo(A) sequence (usually 2 to 5 AMP residues) suggests that adenylation is posttranscriptional. Kramer *et al.*[24] suggested that oligo adenylation of the T_7 early mRNAs is a primitive counterpart of the poly adenylation found in eukaryotic mRNAs.

In considering a function for the polyadenylation of RNA molecules, it is interesting that the precursor of 5S RNA of *E. coli* may contain as many as seven uninterrupted AMP residues at the 3′ end[26]. Because 5S RNA has no known messenger function, a role for adenylation in RNA processing or maturation should perhaps be considered further, particularly since in spite of some recent elegant experiments, a role for poly(A) sequences in mRNA translation in eukaryotes has not been demonstrated[27].

Carbonium ion as ultimate carcinogen of polycyclic aromatic hydrocarbons

RECENT results have indicated that the proximate metabolites of benzo(a)pyrene[1] and benz(a)anthracene[2,3], two typical carcinogenic aromatic hydrocarbons, contain the 1,2-epoxy-3, 4-dihydroxy-tetrahydronaphthalene moiety. This moiety arises from its parent hydrocarbon by formation of an arene oxide, enzymatic ring opening of this oxide to a diol, and then a second epoxidation. As the initially formed arene oxide is opened in a *trans* fashion[4], only two geometrical isomers for the proximate metabolite are possible, and these are depicted as partial structures (I) and (II).
Here I discuss stereochemical features of these two isomers, and indicate that (I) can be predicted to have a much greater chemical reactivity with nucleophiles than (II). This is of interest because of the accepted theory[5,6] that chemical carcinogens act by being metabolised to electrophiles which then react to form covalent linkages with nucleophilic groups present on DNA. Thus it becomes necessary to find metabolites that possess special features which lead to high reactivity in physiological conditions. I describe here that isomer (I) possesses a strategically placed OH group which is expected to assist the epoxide ring opening by neighbouring group participation and thus lead to substantially enhanced reactivity with nucleophiles. Furthermore, this OH group is expected to favour internal ion-pair formation and thus provide an electrophile of the appropriate character to react with DNA *in vivo*.

Both isomers (I) and (II) can exist in two conformations. In each case, however, only one conformation is favoured. The less favoured conformations involve eclipsing of bonds emanating from C_2 and C_3, the more favoured conformation of each isomer is shown in Fig. 1. This shows that the two hydroxyl groups are quasi-axially disposed in (I) and quasi-equatorial in (II). In particular the 4-OH group in isomer (I) is ideally situated for internal hydrogen bonding with the epoxide. This hydrogen bonding leads to a weakening of the C–O bonds on the epoxide and greatly facilitates nucleophilic attack at C_1 or C_2. The interatomic distance from the O of the
Fig. 1 Preferred conformations of partial structures (I) and (II), isomers of the 1,2-epoxy-3,4-dihydroxy-1,2,3,4-tetrahydronaphthalene moiety of the proximate metabolites of carcinogenic aromatic hydrocarbons. Conformations are viewed from a point equidistant from C_2 to C_3 and towards the molecule Viewing point is in the plane of the aromatic ring but remote from it.

epoxide to that in the 4-OH group is 2.5 Å (Dreiding models). Generally epoxides require external acid catalysis for ring opening; however, with isomer (I) the catalysis will be intramolecular and thus the ring opening will occur rapidly under neutral conditions. In isomer (II), on the other hand, the OH groups are not appropriately oriented and such internally assisted epoxide ring opening is not possible, with the result that this isomer will be much less reactive.

Assistance by OH groups in the opening of epoxides by nucleophiles has been recognised in steroids[7] and in the anti-leukaemic triptolide molecules[8]. In each of these examples, the OH group and the epoxide have the same structural and configurational relationships. These same relationships are also found between the 4-OH group and the 1,2-epoxide in (I). There is also conformational similarity as, in all three molecules, the key OH groups are in axial conformations. O–O interatomic distances of 2.7 Å (Dreiding models) and 3.1 Å (X-ray crystallographic work[9]), respectively, in the steroid and triptolide examples above, indicate that the distance of 2.5 Å in isomer (I) is short enough for strong interaction to take place.

The nucleophilic opening of the epoxide of isomer (I) is depicted formally in (III). Nucleophilic attack is possible at both C_1 and C_2 but attack at C_1 is shown because of the steric hindrance that the axial 3-OH group may cause, and because of the probable formation of the well stabilised internal ion pair (IV), in which the O anion is stabilised by the 4-OH group with the positive carbon centre stabilised by the aromatic nucleus. The positive carbon centre is in effect an aralkyl carbonium ion.

III IV
Internal ion pairs such as (IV) have already been shown to occur as the rate-limiting step in the spontaneous rearrangement of arene oxides[10,11] in neutral conditions (which may be accompanied by the NIH shift[12]). In the case of (IV), however, the additional stability provided by participation of the neighbouring 4-OH group is a novel feature. Such additional stability is of course not possible in the analogous zwitterion from (II). The important consequence of the formation of the well-stabilised internal ion pair (IV) from isomer (I) is that this isomer will react with appreciable S_N1 character, that is, as a carbonium ion, rather than by an S_N2 mechanism. As a result it will react with a low sensitivity to the nucleophilic

strength of the incoming nucleophile and small but significant quantities of products from reaction with relatively poor nucleophiles, in the presence of stronger nucleophiles, will result. As DNA has low nucleophilic properties[13], it therefore becomes a necessary feature of an ultimate metabolite that it can indeed react with appreciable carbonium-ion character so that it can alkylate DNA in vivo. The ion pair (IV) will react in this manner and thus has the appropriate electrophilic character to be considered as the ultimate metabolite of aromatic hydrocarbons. By contrast, the isomer (II) as a more typical arene oxide will react with much greater sensitivity to nucleophilic strength[14], that is, in a predominantly S_N2 manner, and alkylate DNA to a negligible extent only. These general concepts have been elaborated previously[15-18].

A more quantitative approach is possible if we arbitrarily assign Swain–Scott[19] substrate constant values s to isomers (I) and (II). By analogy with those other carcinogens which act by way of carbonium ions (for example, isopropyl methanesulphonate[16], $s=0.29$; N-ethyl-N-nitrosourea[17], $s=0.26$; and N-methyl-N-nitrosourea[17], $s=0.42$), the s value of isomer (I) may be 0.3, whereas that of isomer (II) may be 0.9 (for example, glycidol[19], $s=1.00$). Using the Swain–Scott equation[19]

$$\log(k_{GSH}/k_{DNA}) = s(n_{GSH} - n_{DNA})$$

relative rates of reaction with glutathione (a strong biological nucleophile and representative of other SH-containing compounds) and DNA can be compared. Values for the nucleophilicities n of SH groups and DNA are about 5.1 and 2.5, respectively[15], and using these values it may be calculated that isomer (I) would react six times slower with DNA than with glutathione, whereas isomer (II) would react 220 times slower with DNA than with glutathione. Thus isomer (I) will alkylate a small but significant proportion of DNA, whereas isomer (II) will alkylate only a negligible proportion of DNA.

The sites of alkylation on DNA are multiple[1,3], and this also accords with the concept that the ultimate metabolite must have appreciable carbonium-ion character and consequently show poor discrimination for nucleophiles. A general value for the nucleophilicity of DNA was taken above, as it is not possible at this stage to consider any particular sites on DNA as critical. Aromatic hydrocarbons act by causing frame-shift alterations[20,21], in contrast to carbonium ions of smaller molecular size which cause base substitutions. With agents of this latter class, the very weakly nucleophilic[16] O^6 group of guanine may be a critical alkylation site[16,22]. Alkylation by a small group at this site interferes with DNA interstrand hydrogen bonding and base substitution occurs[23]. Alkylation by large groups such as (IV) will clearly interfere more profoundly with the conformation of the double helix, by intercalation (see below) or by a 'base-displacement' mechanism[24], with frame-shift alterations resulting.

The extent of alkylation of DNA in the presence of other cellular constituents such as glutathione will depend not only on the first-order reaction rates described above, but also on the concentration of DNA and glutathione in the immediate vicinity of the ultimate metabolite. As the planar aromatic structure of the rest of the carcinogen molecule is expected to be predominantly intercalated[20,21] with DNA, the concentration of DNA nucleophilic sites will be high compared to SH glutathione and protein sites. The ultimate metabolite thus has characteristics of an affinity label[25] for DNA, in that non-covalent binding encourages more specific covalent binding. The suggestion that many carcinogens and frame-shift mutagens may intercalate and then react covalently has been made[20,21,26-28].

The toxicities of bromobenzene and aromatic hydrocarbons are both mediated by the formation of an arene oxide metabolite, but whereas large amounts of bromobenzene are required to produce hepatotoxicity and this is seen only when glutathione is depleted[29], only very small amounts of aromatic hydrocarbons are required for a carcinogenic effect and no similar

threshold dose exists. This paradox can now be understood in the framework of the above discussion. Thus the 3,4-oxide of bromobenzene reacts in an S_N2 fashion, that is, selectively with strong nucleophiles such as glutathione. Only when body glutathione is depleted by reaction with an equivalent of bromobenzene oxide will this oxide react in appreciable quantity with the next most nucleophilic groups, which are on proteins. The toxicity arises as a result of this covalent reaction with proteins[29]. DNA, a poor nucleophile, is presumably not attacked in the presence of proteins. On the other hand, I have described here how the arene oxide (I) from aromatic hydrocarbons can react as a carbonium ion with DNA, in the presence of glutathione and proteins, and thus no threshold need exist.

Alternatives to the use of tabulated values of distributions in statistical programmes

SPECIFIC values from tables of statistical distributions that vary with degrees of freedom and probability (for example Student's t, χ^2, correlation (r) or variance ratio (F)) are often included as input data, even to large detailed statistical packages[1,2]. Alternatively, the complete tables are held in store. The former makes the program less flexible while the latter uses store inefficiency and is impractical for desk-top computers. A common alternative practice is to use approximate values; thus for example it has been suggested[3] that for a sample number of thirty and more the values of t should be 2.0 when the probability (P) is 0.05. This value for t (30–∞) is within ±2% of the true value and was considered 'a close approximation [suitable] for most purposes'.

The alternative I propose is that simple equations should be formulated to calculate values for such statistical distributions to conserve store space and to make programs more adaptable. The equations should be relatively simple and within the present capabilities of small fixed-function desk-top computers.

As an example, the equation (1) is proposed as a simple approximate solution of Student's distribution of t. It was obtained by a trial and error fitting of the best equation-type

and curve to a graph of the distribution data. In this equation t_{Pn} is the value of t when the probability is P, for example 0.05, and the sample number is n, thus:

$$t_{Pn} = [\exp(k_P/(n-1))] + t_{P\infty} - 1.0 \qquad (1)$$

in which the distribution of $t_{P\infty}$ is given by:

$$t_{P\infty} = -0.1093\,(\log_{10}(1/P))^2 + 1.26\,\log_{10}(1/P) + 0.4941 \qquad (2)$$

The equation giving the values of k_P used to obtain optimum values of t in equation (1) over the range of probability 0.001–0.1 and using the values of $t_{P\infty}$ from equation (2) is given by:

$$k_P = [2.7497\,\log_{10}(1.0/P)] - 1.1994 \qquad (3)$$

This formula (1) provides values of t to within ±5% of the true value[4] for a sample number of between three and infinity and within the range of probabilities $P = 0.1$–0.005; values of t for a sample number of thirty and over are within ±1% of the true t. Values of t over the wider probability range of $P = 0.2$–0.001 were within ±8% of the true t for sample numbers of four to infinity; sample numbers over 30 were within ±3% of the true t.

I realise that when the confidence or fiducial limits thus obtained do not show a clear decision the true tables must be consulted or the equation suggested must be refined; but in most cases these small errors are of little consequence.

The correlation coefficient, r, can also be calculated knowing t for n pairs of samples at the probability P using the equation below (modified from Fisher and Yates[5]):

$$r^2 = t^2/[(n-2)+t^2] \qquad (4)$$

Answers to statistical problems are usually presented in terms of a few standard values of probability, for example the t test confidence intervals. An iterative process could be used with suitable formulae to express the differences between sets of samples in the form of an exact probability, for example $P = 0.06$. With the present formula, results are only reliable within the range of probability 0.1 to 0.005. The use of an approximate formula to calculate the critical values of F could then result in a matrix of probabilities for a comparison of several sets of data. With desk-top computers, the latter step will depend on the demand to make statistical distributions available as fixed functions.

Erratum

In the article "Binding of flexible ligands to macromolecules" by A. S. V. Burgen, G. C. K. Roberts and J. Feeney (*Nature*, 253, 753; 1975), the equation at the foot of the first column on page 754 should read.

$$\Delta F_1 = -RT\ln K_1 = \Delta H_1 - T(\Delta S_{tr} + \Delta S_{rot} + \Delta S_{conf.\,1})$$

and not as printed.

matters arising

Origin of cellular senescence

I HOPE to clarify a point regarding the recent letter of Dykhuizen[1]. He speculated that cellular senescence is the result of a selection process imposed by an organism's need to ensure its survival by limiting the size of atherosclerotic plaques which, he believed, originated from relocated fibroblasts. This is an interesting new view of the limit on fibroblast doubling potential described by Hayflick[2] and others, and the predictions he derives from the hypothesis can be tested experimentally. These include the ultimate cessation of plaque growth when cells at the edge senesce, higher division potential of cells isolated from the centres of plaques, and a correlation between final plaque size and the age of the organism at the plaque's initiation. The fulfilment of these predictions will shed some light on the (probably fibroblastic) origin of plaques but is not critically dependent on an evolved origin for cellular senescence (or doubling potential limit) in the manner Dykhuizen suggests.

The expected observations could be explained, without resort to an evolutionary origin, simply on the basis of known facts. Specifically, cellular senescence manifests itself through a limit on the doubling capacity of fibroblasts; such cells are subject to "contact inhibition" of division[2], and the doubling potential of fibroblasts is related to the age of the donor[3]. Whatever the ultimate cause of cellular senescence or its origin, the behaviour, given these facts, will be the same if plaques do arise from fibroblasts.

The predictions thus do not differentiate between Dykhuizen's explanation of an evolved origin for cellular senescence and a number of other processes which have been postulated as the primary cause of ageing such as error accumulation, a specific genetic programme or the exhaustion of a developmental programme.

DYKHUIZEN REPLIES—The lack of an understandable selective advantage for cellular senescence has been a major criticism of a hypothesis for its evolutionary origin[1]. The main point of my paper[2] was to provide a reasonable evolutionary explanation. To do this, I presented a novel theory of the formation of atherosclerotic plaques. The predictions were meant to test this theory which, if correct, implies that the size of plaques is limited by cell senescence, providing a possible selective advantage to the organism.

Given the assumption that a specific genetic programme could only arise through evolution, the evolutionary origin of cell senescence could be demonstrated by finding a gene, which, when rendered non-functional, allows cells which would normally senesce to become immortal. The error and evolutionary hypotheses could possibly be distinguished by determining the percentage of daughter cells of recently divided cells which go on to divide in a senescent culture and in an immortal culture derived from otherwise similar cells. Orgel[1] suggested that if his error theory holds, then both percentages should be near 50%—slightly less in the senescent and slightly more in the immortal culture. If the hypothesis of evolutionary origin is correct, these percentages should be quite different, say, 20% and 90% respectively.

Further note on electron diffraction symmetries

IN connection with diffraction symmetries it has been suggested[1] that there are two conditions for a centrosymmetric pattern though there is some contention that the first of these conditions is incomplete. As the chief protagonists in this debate we wish to clarify the situation with respect to zero-beam symmetry and reciprocity.

We shall consider first those symmetries observable in convergent-beam zone-axis patterns, that is, restricted sections of reciprocal space distributions disposed on a plane with the geometry of the diffraction pattern. Under these restrictions, a rotation diad along the zone axis completely determines a centrosymmetric pattern for all beams, that is, it is a sufficient condition for the whole pattern and does not require any consideration of reciprocity. (Note that to preserve the diad symmetry consideration must be restricted to either parallel-sided foils lying perpendicular to the incident beam, or else to crystals with boundaries which conform to the diad symmetry.)

This covers the example given by Steeds[2] and requires a correction to the table presented by Goodman[7]. To the last column of entry (2) in the table should be added the words "unless there is a rotation diad parallel to the zone, in which case the pattern will be centrosymmetric". Consideration of reciprocity allows general conditions to be found for zero-beam symmetry which do not apply to the remainder of the pattern as a whole but also give the internal symmetry of each dark-field intensity distribution. Thus, a central mirror or glide plane (condition 1 of Goodman[1]) is a sufficient condition for centrosymmetry in the zero-beam pattern, but not in the remainder of the pattern. For other symmetries, a rotation diad or twofold screw axis, midway between the surfaces and parallel to them, ensures a mirror line in the zero-beam pattern (though not in the remainder of the pattern), perpendicular to the diad or screw axis (though this does not ensure a centre of symmetry in the zero-beam pattern). Higher symmetries than a mirror line or a centre can be built up by combination. Derivation of these rules from the invariance properties of the crystal does not require an explicit solution for the wave function, and can be applied to a crystal of any structure or surface geometry.

From such rules one can proceed to derive a description of a zone-axis pattern for a particular space group. But considerations of electron diffraction always concern crystals that are finite in at least one direction, and the strong interaction of electrons with the crystal potential makes it impossible to ignore the boundary conditions, so the symmetry of the total crystal must, therefore, be considered. The influence of tilted surfaces may be avoided to any accuracy by choosing crystal foils sufficiently parallel-sided and horizontal (say in the range of 0–20°). But the influence of crystal termination in a flat horizontal specimen will mean that the crystal may not have the three-dimensional symmetry of the space group, and in such cases the crystal boundaries used in a symmetry derivation need to be stated.

Experimental limitations need to be considered. Convergent-beam diffraction, and diffraction-contoured micrographs, are practical methods of symmetry analysis with individual limitations. The pattern symmetries can be expressed by two-dimensional point-group symbols, whether investigating two-dimensional projection symmetries or three-dimen-

sional symmetries of the crystal. In the first approximation, the two-dimensional symmetry of the projection at the zone determines the diffraction symmetry and the symmetry of the pattern only has the symmetry of the projection. When measurements are sufficiently accurate, or cover a sufficient angular range, the symmetries must be derived from the three-dimensional space group in the way indicated.

Binding of 25-hydroxy vitamin D_2 to plasma protein in New World monkeys

Belsey *et al.*[1] have shown that the lower potency of ergocalciferol (D_2) compared with cholecalciferol (D_3) in chicks is reflected in a weaker binding of D_2 metabolites to the plasma transport proteins. Further investigations in other species known to be resistant to D_2 were recommended[1] to establish whether similar correlations exist between biological activity and binding to transport proteins. Since New World primates (Cebidae) utilise D_2 less efficiently than D_3 (refs 2–4) we examined the transport proteins in four species of New World monkeys to test whether they also discriminate against D_2 metabolites.

A competitive protein binding assay involving the displacement of ^{3}H-25-OH-D_3 from the specific plasma transport proteins by 25-OH-D_2 and 25-OH-D_3 was used to test the relative binding of these two metabolites of D_2 and D_3.

In the assay system with plasma from the monkey *Cebus albifrons*, increasing amounts of 25-OH-D_2 and 25-OH-D_3 produced similar reductions of the bound ^{3}H-25-OH-D_3 (Fig. 1) indicating equivalent binding of the two steroids by the *C. albifrons* transport protein. A similar result was obtained for the three other primates tested—*C. capucinus, Aotus trivirgatus,* and *Callithrix jaccus.* Old World monkeys (Cercopithecidae) utilise D_3 and D_2 with equal efficiency[3] and in the three Old World primate species we studied (*Erythrocebus patas, Macaca mulatta,* and *Papio anubis*) the transport proteins exhibited equal affinity for 25-OH-D_2 and 25-OH-D_3.

There are differences in the type of protein used by the species examined in this study for vitamin D transport. *C. albifrons* and *C. capucinus* use albumin[6] whereas the two other New World and
Fig. 1 Competitive displacement of ^{3}H-25-OH vitamin D_3 from *C. albifrons* plasma with increasing amounts of non-labelled vitamin D analogues. Each point is the mean of two determinations ○, 25-OH-D_2; ●, 25-OH-D_3.

the three Old World primates use an α-globulin fraction[6]. The seven primates studied only have a single transport protein[6] whereas the chick has two proteins which exhibit β-globulin mobility on gel electrophoresis[6,7]. Although two types of protein are used for vitamin D transport in these primates their binding properties for 25-OH-D_2 and 25-OH-D_3 are similar.

The results obtained for the steroid binding properties of the New World monkey transport proteins are in contrast to those of the chick proteins which do discriminate against D_2 metabolites[1], an observation we were able to confirm. From this, it would seem that the resistance of New World primates to vitamin D_2 is a result of other differences. These may involve inefficient binding of D_2 and 25-OH-D_2 by intracellular vitamin D binding proteins in liver or kidney respectively or discrimination against the active kidney metabolite 1,25-$(OH)_2$-D_2 by the binding proteins present in target organs such as muscle, gut and bone.

The variations between the binding properties of New World primate and chick transport proteins for 25-OH-D_2 illustrate the difficulty of postulating a general theory of D_2 resistance. These differences confirm that the process of discrimination against D_2 in species resistant to this vitamin cannot be explained uniformly by the properties of the plasma protein as evidenced by the chick. It seems, therefore, that a wider survey of vertebrates known to be resistant to D_2 is required to correlate the random observations made in individual species.

Ultraviolet viewing with battery-operated television camera

Lavigne and Oritsland[1] have shown that ultraviolet photography can be used usefully for the detection of white animals on snow. Polar bears, for example, ordinarily match their background and may be difficult to spot, certainly from a distance, but when photographed in the near ultraviolet band of the electromagnetic spectrum (300–400 nm) they appear as black bodies, sharply contrasted against the snow. The technique is said to have application for the remote sensing of polar bears in the field. We suggest that ultraviolet detection can also be carried out conveniently with a television camera. Such cameras are intrinsically sensitive to the near ultraviolet band, and to be used for ultraviolet viewing need only be outfitted with an ultraviolet-transmitting lens and filter. We have used the technique for viewing ultraviolet contrast patterns on flowers and butterflies[2], but it should also lend itself to detection on snow of animals which absorb in the ultraviolet. Though conventional, portable video systems, suitable for use in the field, include both a camera and a recorder, the recorder can be disconnected easily, and the camera can be converted to a self-contained viewer if it is fitted with a battery pack attached to the housing. The disconnection of the recorder decreases the vertical resolution of the camera's monitor (because of the loss of scan synchronisation pulses from the recorder), but the quality of the image is adequate for most purposes (full resolution can be restored by the installation of an oscillator and appropriate divider circuits on the camera). Such cameras provide compact, manageably light, and relatively inexpensive, ultraviolet image transducers.

reviews

THERE comes a stage in the development of any powerful new experimental technique, microscopical or otherwise, when its value for research is so well established that an authoritative survey is essential to its full exploitation in science and technology generally, beyond the circle of enthusiastic pioneers. Transmission electron microscopy has long reached that position, and the need is being satisfied by a number of monographs and treatises, including Professor Hayat's *Basic Electron Microscopy Techniques* (a conveniently short volume) and his *Principles and Techniques of Electron Microscopy: Biological Applications*, published by the same house. Whether his *Electron Microscopy of Enzymes* (two volumes, so far) is equally timely I am not qualified to judge. But I am in little doubt that a similar treatment of the biological applications of scanning electron microscopy is at best premature and at worst likely to be misleading. There simply has not been enough work done in the subject to serve as basis for it. Only a limited number of biologists throughout the world are seriously applying themselves to the problems of specimen preparation and observation, as distinct from the exploratory use of the instrument.

However useful it may be to newcomers in the field, the title borne by Hayat's new series covering scanning electron microscopy is a misnomer. In effect, it is a journal of biological scanning electron microscopy, largely devoted to articles describing the work of the individual contributors. True, there is an article descriptive of the instrument itself, compressed into 42 pages and failing to mention the two major treatments by Hearle *et al.* (1972) and Oatley (1972). There are also excellent descriptions of the critical point drying technique (60 pp.) and of the preparation of stereomicrographs (14 pp.), both of which are deserving of a wider readership. Nearly all the remaining 19 articles are short accounts (averaging 17 pp.) of special applications of the instrument in the study of spores, leaf surfaces, plant cell walls, wood, intracellular structures, marine teleosts, ciliated epithelia, lung, bone, and so on. To do him justice, the editor is quite frank in his preface to the second volume: "This treatise [*sic*] departs from the tradition that a book on methodology presents only the contemporary consensus of knowledge. It is written by scholars [who have] anticipated the potential usefulness of a new method."

Microscopy
V. E. Cosslett

Principles and Techniques of Scanning Electron Microscopy: Biological Applications. Edited by M. A. Hayat. Vol. 1: Pp. 273; £11.95. Vol. 2: Pp. xii+171; £10.60. (Van Nostrand Reinhold: New York and London, October 1974.)

Principles and Techniques of Electron Microscopy: Biological Applications. Edited by M. A. Hayat. Vol. 3: Pp. xii+321; £11.35. Vol. 4: Pp. xi+216; £10.60. (Van Nostrand Reinhold: New York and London, November 1974.)

If I had to advise a library on its buying policy, my opinion would be that Volume 1 may be worth its price as an introduction to the subject if *The Use of the Scanning Electron Microscope* by Hearle *et al.* is not already on the shelves, but that Volume 2 should only be bought if urgently requested by local biologists. They would do better, however, to consult the original papers in their field of interest, most, if not all, of which they will find listed in the *Bibliography on Biomedical Applications of Scanning Electron Microscopy* compiled by Boyde *et al.* and published in *Scanning Electron Microscopy* 1973, the proceedings of one of the annual meetings on the subject at the Illinois Institute of Technology.

Principles and Techniques of Electron Microsopy: Biological Applications (Volumes 3 and 4) can be viewed more favourably. This series, now planned to extend to eight volumes, sets out to cover the whole range of knowledge involved, including the operation of the microscope itself in its various modes.

The current volumes contain seven and eight articles, respectively. They vary greatly in nature and style, from a broad survey of a topic to a monograph on an author's special field of work. Understandably, the latter form is usually the more readable and useable, and includes articles on high resolution, dark-field microscopy, in-focus phase contrast and stereological techniques in Volume 3, and in Volume 4 on optical shadowing, relative mass determination in dark-field, microscopy of single cultured cells, denaturation mapping of DNA and the examination of polysomes from cardiac muscle. At the other extreme lie collections of recipes for specimen preparation: selective staining of molecules, sub-

cellular fractionation in the ultracentrifuge, and critical point-drying (surely the hypen is misplaced?) in Volume 3; and ultramicroincineration in Volume 4. The latter volume also contains a comprehensive if uncritical account of preparatory [*sic*] methods for electron probe analysis by X-ray spectrometry. Two articles fall outside these categories: a general introduction to the electron microscope and its operation in Volume 3 and an account of methods for counting virus particles in Volume 4.

Granted that the subject is now so wide ranging as not to be encompassed in a treatise by a single author, the best method of covering it by multi-authorship has to be solved. The treatment planned by the editor of this series falls somewhere between two others now becoming available: the encyclopaedic *Methodensammlung der Elektronenmikroskopie* (Wissenschaftliche, Stuttgart) and *Practical Methods in Electron Microscopy* (North-Holland, Amsterdam). The former breaks down electron microscopy into a great number of sub-topics, treated at a high level of expertise in relatively short compass, whereas each volume of the latter comprises two or three long articles in which a rather broader subject is dealt with in greater depth. Dr Hayat's series covers much the same subject matter, but unevenly and rather randomly. Apart from the first two volumes, which described basic preparative techniques, the two under review (and the remaining four as listed) contain an unrelated assortment of contributions. Some of these are by acknowledged leaders in a subject, others by recipe collectors. The level of approach varies from elementary to advanced; the proof reading varies from excellent to execrable (even the editor's name is misspelt in one place); and the current-awareness varies from yesterday to the day before. In such a rapidly moving subject it is regrettable to find few references in Volume 3 later than 1970 or in Volume 4, later than 1971, apart from cross-references within the series.

That said, these volumes have the merit of purveying in compact form a great deal of information, some of value to present practitioners and most of help to the beginner. He, she or they are likely to decide that one or the other of them is sufficiently valuable to be bought, even at these rather high prices. The whole series ought to be available in any biological laboratory making regular use of the electron microscope. □

Welcome addition to multivariate analysis

Discrete Multivariate Analysis: Theory and Practice. By Yvonne M. M. Bishop, Stephen E. Fienberg and Paul W. Holland. Pp. x+557. (MIT Press: Cambridge, Massachusetts, and London, March 1975.) $27.50.

DISCRETE data, in which each variable takes one of a limited number of possible forms, arise frequently in many fields. Multivariate analysis of such data is required when the joint distribution of several variables is to be studied. The present book gives an account of statistical methods for these problems. It concentrates largely, although not entirely, on an approach in which the log frequencies in cells of a multi-dimensional contingency table are represented in some simple form, the so-called log linear model. To an appreciable extent the book is based on the authors' earlier important contributions to this topic.

The discussion is lucid and very leisurely, excellently illustrated with applications drawn from a wide variety of fields. A good part of the book can be understood without very specialised statistical knowledge. It is a most welcome contribution to an interesting and lively subject.

After an introductory chapter, structural models for multidimensional discrete data are described, and then maximum likelihood methods of estimation are developed; this is followed by a consideration of the methods used for testing degree of fit. Methods for incomplete data (missing cells) are discussed at length. There is an interesting chapter on estimating the size of a closed population, in which the usual methods for the analysis of a multiple capture–recapture census are modified to take account of possible dependencies between the samples on successive occasions. Further chapters include discussions on Markov models for assessing change and on the special problems of 'square' tables. The book ends with two chapters on approaches other than that of the log linear model and chapters on pseudo-Bayes estimates (that is, on smoothing tables), on sampling models and on mathematical aspects.

The scope of the book is rather less than might have been expected from its title. For instance, there is no discussion of latent structure analysis or of the difficult problems of analysing multivariate discrete data in connection with numerical taxonomy.

I have one general criticism, which, though to some extent a matter of taste, seems to me important. The authors barely mention the distinction between response variables (dependent variables) and explanatory variables (independent variables). Yet in quite a number of their examples the point at issue seems to concern how variation in one of the variables is explained by the other variables, which is a univariate and not a multivariate problem. Even if the detailed analysis is little affected, incisive explanation of conclusions is much easier for univariate problems. At a more technical level the authors have ignored the fact that in some—but not, of course, all—of their problems conditioning on ancillary statistics is possible. **D. R. Cox**
The Virgin Mary, hands crossed in the gesture of humble submission. A wood carving from the Marienalter of Herrgottskirche in Creglingen, Germany. Photograph taken from *Silent Language*, by Macdonald Critchley. Pp. vi+231. (Butterworth: London, April 1975.) £9.50.

Fundamentals

Fundamentals of Mathematics. Vol. 1: *Foundations of Mathematics/The Real Number System and Algebra.* Pp. x+549. Vol. 2: *Geometry.* Pp. xi+685. Vol. 3: *Analysis.* Pp. xiii+541. Edited by H. Behnke, F. Bachmann, K. Fladt and W. Suss. (MIT Press: Cambridge, Massachusetts, and London, 1974.) $15.95 each volume; $40.00 the set.

THIS work stands alone; it is a unique survey of the whole field of pure mathematics, with emphasis on the basic ideas and their interrelationships. For its origin, we must go back over 20 years. In 1954 the International Commission for Mathematical Instruction, at a meeting in Paris, chose the scientific foundations of instruction in mathematics as one topic for the 1958 International Congress in Edinburgh. As a result, the German section of the Commission began Volume I of this work. During its subsequent development authors from various European countries contributed, and it became clear that the material would be important not only for teachers and lecturers but also for research mathematicians. The original publication was in German, and the volumes now reviewed consist of a translation based on the second German edition of 1962; it incorporates various improvements and exercises designed to bring the account up to date.

Each chapter has been written by two authors, one a university research mathematician, the other "a teacher of long experience in the educational system". As a result, over 80 authors have contributed.

Volume I consists of a part on the foundations of mathematics and a part on arithmetic and algebra. Volume II deals with geometry, and consists of 16 chapters covering both the foundations and the analytic treatment of this aspect of mathematics. Worthy of special mention are the chapters on geometrical constructions and on polygons and polyhedra. Volume III is concerned with analysis and includes 14 chapters.

No mathematical specialist can consult the work without becoming acutely aware of the tremendous breadth of mathematical thought and discovery. The student, contemplating research in some area of the subject, would do well to read, in these volumes, of the relationship between that particular area and the subject at large; for it is a distinctive feature of the work that it emphasises the connections between different branches of mathematics.

Many people, including a lot of mathematicians, find it difficult to see perspective in mathematics. To such, the last chapter, on the changing structure of modern mathematics, is to be commended. Here is a very clear account, carefully traced, of what has been happening in recent decades. It is all summed up in the expression "axiomatic way of thinking". There is reference, of course, to the Bourbaki movement in France, and to the development of the axiomatic method in geometry. Then comes the change in algebra, namely the breakthrough of axiomatic algebra (covered particularly well by E. Artin and Emmy Noether). Finally, the great achievements of the axiomatic method in analysis are traced, although these considerations are tinged with an element of doubt as to whether the axiomatic change in analysis will ever be as complete as that in algebra.

No serious mathematician can afford to neglect these volumes. To read them is an experience; and, at the end, the reader will be more aware of the abiding serenity of his subject. **L. S. Goddard**

The Heritage of Copernicus: Theories "Pleasing to the Mind". (The Copernican Volume of the National Academy of Sciences.) Edited by Jerzy Neyman. Pp. 542. (MIT Press: Cambridge, Massachusetts, and London, 1974.) n.p.

THIS book is not about Copernicus, nor about the postulated revolution to which he has given his name. Rather, it is a collection of 24 essays, by various hands, dealing with various other postulated 'Copernican' or 'Quasi-Copernican' 'revolutions' in astronomy, cosmology, biology, chemistry, physics, mathematics, probability theory and technology. The book is intended for the general reader, who will need to have a rather large technical vocabulary, or access to a rather large and up-to-date dictionary. None of the contributors seems to be a professional historian of science.

Many of the 'revolutions' described are merely good pieces of traditional science—such as Shapley's work on our Galaxy—and almost all the references to Copernicus' own work show a degree of incomprehension that makes the book highly ambiguous as a tribute.

The most interesting essays are those which pay least attention to Copernicus or to 'revolutions': one by Geoffrey and Margaret Burbidge on some of the problems facing modern cosmological theories, and one by Stanley L. Miller on "The First Laboratory Synthesis of Organic Compounds under Primitive Earth Conditions".   **J. V. Field**

The Laue Method. By Jose Luis Amoros, Martin J. Buerger and Marisa Canut de Amoros. Pp. xi+375. (Academic : New York and London, March 1975.) $37.00; £17.75.

THE Laue technique, although the oldest used by X-ray diffractionists, was early superseded in many areas of structure analysis by methods based on monochromatic radiation and moving crystals. But it has remained a useful technique in metallurgy and crystal physics, especially, though no thorough presentation of its potentialities has appeared for about 40 years. This book aims to fill the gap.

Chapter 1 is historical, chapters 2–8 are written especially for the numerous users who have had no formal training in crystallography, and chapters 9–13 are aimed at the specialist. Structure analysts who normally only take Laue photographs by accident will find this book well worth reading, partly for the clarity of its presentation, but also because it presents some fresh and some neglected ideas. The novel suggestion for the use of the method in crystallochemical analysis seem to me to be rather too opti-

mistic, but the discussion of the idea that cylindrical Laue photographs can be used to determine the symmetry and orientation of an arbitrarily set crystal will well repay study. So too will the sections which discuss the methods used in the study of the diffuse scattering which results from thermal motion, disorder or crystal imperfections.

The last chapter purports to present a new method of interpreting the photographs; I can remember it being used, however, for teaching the topic at a summer school in 1947 and can attest to its utility.   **D. Rogers**

Books brief

Design Theory of Fluidic Components. By Joseph M. Kirshner and Silas Katz. Pp. xi+479. (Academic : New York and London, January 1975.) $45.00; £21.60.

AT present the list of books concerned with the relatively new technology of fluidics is quite short. Kirshner and Katz have made a valuable addition to the list. The initial chapters about the properties of fluid filled transmission lines and jet flows are particularly good and the bibliographies given after each chapter are extensive and well up to date. The authors have rightly restricted their attention to devices with non-moving parts and devote a complete chapter to each main type and their performance characteristics (these include the impact modulator, the vortex triode, the beam deflection amplifier, the bistable switch and the transition NOR). The appendices contain data on air filled transmission lines and also computer programs for calculating the response of such lines to various inputs. These will be very useful to system designers. Likewise, newcomers and students will find the list of problems following most chapters helpful, though for some reason the answers are not given. **Terry Hughes**

Mycotoxins. Edited by I. F. H. Purchase. Pp. xiii+443. (Elsevier Scientific: Amsterdam, Oxford and New York, 1974.) Dfl.115; $44.25.

THE discovery of aflatoxin 15 years ago attracted the interest of many scientists to the field of the mycotoxins. It was indeed fortunate as previously very little had been known of the chemistry and mode of action of the mycotoxins in spite of numerous ancient descriptions

of the massive poisonings of people and domestic animals by these fungal metabolites.

This book, addressed primarily to investigators and students, contains ample information on different aspects of studies on mycotoxins. Contributors have not followed precisely unified criteria in their presentations and some chapters are treated from widely different points of view. Furthermore, there are four chapters concerned with trichothecene mycotoxins, which results in some overlapping in the information on these compounds.

The authors have been chosen well. Most of them are leading authorities in the subjects which they write about, and the coverage is very good although there are few data dating from later than the end of 1972.

The presentation and typography of the book are excellent.

This volume should be useful not only to mycologists and scientists interested in mycotoxins but also to pathologists and experts in bromathology and toxicology. The book might be very encouraging to investigators interested in the mode of action of mycotoxins, since little work has been done on this aspect of these compounds.   **David Vazquez**

Handbook of Genetics. Vol. 1: *Bacteria, Bacteriophages and Fungi.* Edited by Robert G. King. Pp. xvi+676. (Plenum: New York and London, 1974.) $44.50.

THIS book, the first in a series, aims to review organisms which have been extensively used by geneticists. It is an excellent collection of review articles interspersed with techniques, gene symbols and chromosome maps for selected bacteria, bacteriophages and fungi. The introductory article on a classification and evolutionary scheme for all organisms, although interesting and relevant to the series as a whole, seems out of place as it makes no reference to techniques such as %G+C and numerical taxonomy. Most of the articles are of a high standard and contain a wealth of technical and background material. The total omission, however, of any reference to the extensive genetical work on *Coprinus lagopus* in an article entitled '*Coprinus*' is difficult to understand but this is an isolated case and the rest of the material is well balanced. The usefulness of the indices could have been improved by giving textual pages rather than bibliographical pages in the author index and by greater cross referencing in the subject index.

In spite of these relatively minor criticims and the high price, this book should become a basic reference work for research workers and teachers in microbial genetics.   **B. W. Bainbridge**

obituary

Robert Alexander Houstoun, a leader in the optics field, died on May 4 at the age of 92.

A student of Glasgow, he pursued his studies at Cambridge and Göttingen, where he obtained his PhD. Joining the staff of Glasgow's natural philosophy department in 1906 he continued his research in optics till he retired in 1948 and for some years after as an Honorary Research Fellow. His research interests were varied but he is best recalled for his work in colour vision and the measurement of the velocity of light in air and water by the piezo-quartz shutter method, which he developed. He also found time to write a considerable number of successful books. His *Treatise on Light,* first pub-lished in 1915, was for a long time the standard work in its field, and a considerable number of published papers flowed from his pen from 1904 to the end of the 1960s.

Eric H. Lenneberg, professor of psychology and neurobiology at Cornell University, has died at the age of 53.

At the time of his death, Dr Lenneberg was working on a clinical research project in neuropsychology at the Westchester Division of New York–Cornell Medical Center, after having joined Cornell in 1968. His major scientific achievement was considered to be the proposal, first advanced by him in the 1950s, that the human capacity for language could be explained only on the basis of the biological properties of the brain and vocal tract. He had summarised his experiments and views in his book *Biological Foundations of Language,* published in 1967. Dr Lenneberg was born in Germany and after spending much of his youth and childhood in Brazil, went to the US in 1945, eventually obtaining degrees from Columbia and Harvard. He joined the staff of Harvard, and later carried out basic research on language development in defective children at the Children's Hospital Medical Center in Boston while on the staff of the Massachusetts Institute of Technology. From 1967–68, he was professor of psychology at the University of Michigan.

announcements

Awards

The Royal Institute of Chemistry has made the following awards: **Meldola Medal and Prize** for 1974 to **P. J. Derrick** for contributions to the development of field ionisation kinetics and mass spectrometry; **Beilby Medal and Prize** for 1975 to **P. R. Swann** for work in electron microscopy of metals alloys and phase transformations.

Forever amber on manipulating DNA molecules?

LAST weekend saw a hundred scientists descending on Oxford to discuss with representatives of the Research Councils and the Department of Health and Social Security the problems of experimentation in the 'genetic engineering' field. It is now six months since the Ashby report was published and gave what we described at the time as an amber light to such experiments. The Ashby working party took evidence from more than twenty workers or potential workers in this field, but was itself constituted of scientists who in the main did not include those using the techniques and who might therefore have had a direct interest in the conclusions. Ashby reported that "subject to rigorous safeguards [spelt out in the report] these techniques should continue to be used because of the great benefits to which they may lead". But how to implement these safeguards, and how to implement them quickly?

Several participants were at pains to point out the intellectual pressure that is building up to get moving again in this field. It was wrily conceded that more impatient scientists were already under way and although there was no evidence that they were conducting experiments in an irresponsible way, their action was causing considerable frustration amongst those waiting for more formal guidance on safety. It is, as one participant put it, rather like the vivisection laws—until society has spoken it is left to the vagaries of individual consciences. And there is obvious pressure to go ahead—participants, on being asked whether they, as individuals, would wish to perform such experiments within the next two years, said 'yes' in considerable numbers.

If the issue were as simple as that, then the most obvious course would be to place as much pressure as possible on the Department of Education and Science, with whom the Ashby report now resides, to get cracking and persuade the government, amidst all its obsessions with consensus in inflation-control to give a moment's thought to the consensus in hazard-control, and implement the safeguards. (The meeting overwhelmingly endorsed the Ashby recommendations on strict containment.) But there are complicating factors.

First, the consensus amongst scientists that all could be made and kept safe is no longer accepted as the watertight guarantee that it once would have been. There has been a certain amount of self-satisfaction that where-

as the Asilomar conference was a meeting of those with a direct interest in the experiments, the Ashby report came from those who could take a broader view. But broad enough? Technicians have an obvious interest in safety, and their concern, expressed through their union, will not necessarily mesh with the scientists' desire to get moving as soon as possible. The pharmaceutical and agricultural industries, barely represented in the Ashby testimony, may at some time in the future wish to switch from laboratory to large-scale operations; they have an obvious interest in ensuring that the safeguards in any legislation make sense on the larger scale. And what about members of the public? Ashby went out of its way to ask 'how can the social values of the community at large be incorporated into decisions on science-policy?', and tried to present the report in a widely-accessible form. But how can the government assess what the community feels on this subject?

Second, there is doubt in some scientists' minds about the scope of any proposed code of practice. There was clear agreement at Oxford that Ashby and Godber should not be confused—that is, that there should be a difference in governmental approach towards the as yet unpredictable hazards of artificial recombinant DNA molecules and the predictable hazards of pathogens with their established handling procedures. But how open-ended should the discussion on unpredictable hazards be left? Some believe that the dangers in currently-known methods may seem slight in comparison with the dangers in methods only dimly foreseen. On the other hand, to widen the debate, the administrators in particular believe, would be to diminish the chances of a quick response from the government.

It may not be an issue of great substance but we feel that the exclusion of the scientific press from the Oxford meeting was unfortunate. We hardly believe that any dark conspiracies were hatched, but there is broader interest amongst scientists in this issue than in almost any other at present, and since one of the purposes of the meeting was to inform and educate, it should be said that an informed and educated press ought to have been one of the (admittedly lesser) aims of the organisers. It is difficult to accept the argument that participants would speak less freely with the press on hand, when there were already a hundred pairs of ears around. □

Man and the Biosphere

Tunisia: MAB project area No. 3 (grazing lands) examines the problems of rangelands supporting three million 'sheep units'.

When a conscientious government department requests advice on the potential environmental effects of a proposed agricultural development scheme for an area of tropical forest or of the construction of an irrigation dam in an arid area, it is a chastening experience for the "scientist" to have to admit that he has no hard and fast advice to give. Contrary to what most people believe, we neither know for sure what should be done nor, equally important perhaps, what should not be done in these kinds of situations. For, paradoxically, although a great wealth of scientific information is available, much of it is not used and, in fact, in the mono-disciplinary form in which it has been compiled, is unusable within the context of development planning. In spite of the years of work that have gone into the study of forests, deltas and estuaries, arid zone grazing land and irrigation problems, and so on, the findings that have emerged, valuable as they are, do not provide practical answers to the sort of questions governments and decision-makers are asking, because the research approach has not been geared to consideration of the man/environment system involved. It was precisely to resolve this paradox that UNESCO's Man and the Biosphere (MAB) Programme was conceived in an attempt to develop an integrated research approach to the management problems arising from the interactions between human activities and natural systems. Michel Batisse, Director, Department of Environmental Sciences and Natural Resources Research, UNESCO, reports.

THE response to MAB at government level, particularly from the developing countries, was favourable from the start, yet it requires a very long time and much patient effort to get any project moving on a reasonably harmonious front at the international level. The reasons for this inertia are easy to understand. They relate to the traditional suspicion in the older countries of anything 'supranational', to the difficulties of fully conveying the concepts underlying a common objective in a multilingual and multicultural world, and to the mere fact that not all countries are, to put it mildly, at the same stage of development and at the same level of capability. For those with no experience of the intricacies of international cooperation, this slow movement is thoroughly frustrating. For those aware of the problems, it is always a pleasant surprise when some progress is actually made.

The MAB Programme provides a good illustration of this. It originated from the conference in September 1968 on "the scientific basis for rational use and conservation of the resources of the biosphere", which could hardly have dealt with a subject of greater concern to all men and countries. Yet it took some two years before the programme could be actually formulated and officially launched—in November 1970—by the General Conference of UNESCO. And it took another two years of misunderstandings and foot-dragging before it was unanimously endorsed by the Stockholm Conference on the human environment. What had been initiated through the enthusiasm of working scientists had to find its way through the tortuous pathways of politics and the minefields of official science before it could be presented to the world with all the necessary visas and blessings.

This has now been done, and another major step forward has since been achieved; last September, in Washington, DC, the International Coordinating Council which supervises the Programme recognised that the preparatory phase was over and that MAB could now enter its operational phase.

Although MAB was discussed during the summit talks between the USA and the USSR last year—to the great bewilderment of the chancelleries when they discovered this strange acronym in the official communiqué—little publicity has so far been given to the Programme in the scientific press and its actual scientific content is not known to many people potentially interested in it. The general objective has been formulated as follows: "to develop within the natural and social sciences a basis for the rational use and conservation of the resources of the biosphere and for the improvement of the relationship be-

tween man and the environment; to predict the consequences of today's actions on tomorrow's world and thereby to increase man's ability to manage efficiently the natural resources of the biosphere".

To achieve this ambitious objective MAB has adopted an integrated, global approach to the analysis of ecological systems, their structure and functioning and their mode of reaction when exposed to human intervention. This approach stresses the impact of man on the environment but also the impact of the environment on man.

The MAB Programme comprises fourteen project areas forming a kind of research matrix in which the main ecological systems and physiographical units (tropical forests, grazing lands, mountains, islands, river basins and estuaries, and so on) interact with major activities or processes such as conservation of genetic resources, use of pesticides and fertilisers, major engineering works or demographic changes.

The MAB Programme is intergovernmental in structure: it is controlled by an International Coordinating Council consisting of representatives of 25 member countries, sitting together with representatives of the organisations of the UN system interested in the Programme (UNEP, the FAO, the WHO, the WMO and UNESCO) and representatives of ICSU and the IUCN. The contribution of each country to the international programme is developed through National Committees, where normally scientists from universities and research institutions sit alongside representatives of government departments. The general secretariat is provided by UNESCO.

Today, after the somewhat tedious but all-important period of preparation during which working groups and expert panels hammered out research guidelines for all projects, the stage is set for actual implementation of cooperative programmes at the regional and international level. Some 80 MAB National Committees have been established, not all of them perfect but most of them keen to move ahead.

Underlying the Programme are three concepts on which its approach to research is based: MAB is problem-oriented, it is interdisciplinary and it aims to provide both immediate and long term scientific, economic and social benefits, in particular to the developing countries.

A problem-oriented approach to research has the twin advantages of projecting the practical face of science to government leaders and of involving decision-makers in the formulation and implementation of projects. Within MAB, the scientist who has traditionally been concerned with the question

"what happens?" in an ecosystem is asked to go a step further and attempt to answer the question on which the decision maker will base his judgement, that is, "what would happen if . . . ?"

Work now being undertaken in Tunisia within the framework of MAB Project Area No. 3 (grazing lands) provides a good example of this problem-oriented approach. The arid and semi-arid areas of southern and central Tunisia cover 65,000 square kilometres and account for some 40% of the national territory. Intense pressure is being exerted on this area by the 3 million "sheep units" it harbours (the various categories of domestic animals being statistically accounted for in terms of sheep equivalents) and by a human population of 1 million urban and 2 million rural inhabitants. The sort of information Tunisian planners want is: what is the carrying capacity of the rangelands and how can it be improved? How far should the development of intensive farming be improved? How far should the development of intensive farming be encouraged? What would be the ecological effects of the introduction of improved fodder crops? The answers provided will have a major bearing on the ecological, economic and social future of the country, and will be of obvious interest to other countries in the Mediterranean area having similar conditions.

The interdisciplinary approach is, by the very nature of things, essential to the MAB programme, but there are considerable difficulties in creating interdisciplinary research teams and in integrating fully the results achieved.

It is easy enough to talk about the need to break down the barriers between disciplines, but many of these divisions have a logical and practical basis. The units of analysis employed often differ from one discipline to another. Socio-cultural studies are usually based on social units—kin groups, tribes, communities—whereas ecological studies may be based on sample areas of a few hectares or even less. Problems of the duration of research also arise. A botanist may be interested in the problem of biomass changes in a plant community during a single growing season, whereas the sociologist may need to examine migration trends over a number of years. If an interdisciplinary effort is to succeed it must be planned as such from the start; each research worker must be prepared to adapt to the methods of others and all must possess the flexibility of mind and the team spirit that this approach implies.

The vital importance of interdisciplinarity is well exemplified in two current MAB projects. In the study on population and environment in the eastern

islands of Fiji (MAB Project Area No. 7—island ecosystems) the research team consists of ecologists, pedologists, a nutrition expert, human geographers, a biogeographer and marine biologists. The objective is to understand the actual relationships between population levels and natural resource use under well established conditions. In Hong Kong, where an integrated ecological study of a large urban settlement is being carried out with Australian support (MAB Project Area No. 11—urban systems), the spread of disciplines is even wider; the fifty-strong research team ranges from biologists and hydrologists to sanitary engineers, architects and town planners, physicians and psychologists, cultural anthropologists and sociologists. The team also includes a small unit which specialises in the study of the problems of research integration. The objective is, of course, to understand the functioning of the urban system as a particular kind of ecosystem, in order to provide a sounder basis for its planning and management.

It is interesting to note that—in contrast with most previous international research efforts—the MAB Programme stimulates a particularly strong interest in the Third World countries. Determined to shake off the vestiges and constraints of their past, they are eager to exploit their natural resources for their direct benefit. But they are more aware than one thinks of the difficulties involved in changing traditional methods of land use or introducing foreign technologies. They seem therefore to have quickly realised that MAB can offer them tools with which to formulate important aspects of their development planning. A typical example is the problem of the tropical forests. About half the world's forest area is located in three main regions: tropical Africa, tropical America and South-east Asia. Tropical forests are estimated to cover an area of some 2,000 milion hectares, of which some 850 million hectares can be regarded as tropical rain forests. Forests are seen by developing countries of the tropics as largely unexploited areas for colonisation and agricultural development as well as a potential source of foreign exchange. For the developed countries they represent a readily available source of relatively cheap timber.

Widespread modification or destruction of tropical forests is of concern to scientists because of their ecological diversity, complexity of structure and richness in species. Within the tropical region, intimate relationships exist between the indigenous populations and the forest, and the forest is important for soil and water conservation. Because of their extent, biomass and dynamics, tropical forests also play an important yet little understood role in the global

ecological and atmospheric balance of the biosphere.

The importance of research in this field was recognised from the inception of MAB and a general formulation of the practical research problems involved was made in November 1971 under MAB Project Area No. 1 (tropical and sub-tropical forest ecosystems). The next step was to convene in May 1972 an *ad hoc* panel of experts to elaborate the scientific content of research in this area and to consider approaches and plans of studies that could be recommended to the MAB National Committees concerned. This was followed up by an international working group meeting held in Rio de Janeiro in February 1974 which was given the task of identifying problems of common concern and of examining research proposals presented by the different governments that would involve international cooperation. The working group was also asked to discuss the requirements for regional coordination of research, harmonisation of methods and measurements, the exchange of information, experience and personnel, the training of specialists and technicians, and the sharing, storage and processing of data. Finally, regional meetings have been organised in Kuala Lumpur and Mexico City at which national representatives proposed specific pilot field projects for the regions concerned. Similar regional meetings are to be held in Kinshasa and Varanasi later this year.

At the same time regional long term training courses on tropical ecology have been organised in Venezuela, the Philippines and Kenya to contribute to the training of ecologists who could be used in the development of research and management programmes in the three regions concerned. Finally, a world-wide synthesis of knowledge on the tropical forest ecosystems and their rational use and conservation is being prepared for publication in 1976 so as to provide a common background and conceptual basis for MAB Project No. 1.

As a result of this strategy, one can envisage within the near future the development of a network of pilot schemes for integrated ecological research in the three tropical forest regions of the world, involving the exchange of research personnel, providing field training, and forming part of an inter-regional co-ordinated effort to help master one of the most challenging problems of the tropical world. A similar 'strategy' is being applied for other MAB project areas, particularly those on grazing lands and urban systems.

Is MAB now really going to take off? At the last session of the UNESCO General Conference, where some 130
Hong Kong: chosen by MAB for an integrated ecological study.

governments represented were sharply divided on several issues, MAB received unanimous support. The political obstacles therefore seem minimal. Governments, particularly those of the developing countries, are very interested and those scientists already involved in the Programme are committed to its success. The major difficulties are probably elsewhere. They lie primarily in the difficulties—lack of scientific infrastructure and of personnel—developing countries face in playing their role in a world-wide programme, which would be meaningless without their participation. This can only be mitigated through a vigorous training and technical assistance back-up effort in which all donor countries and international organisations concerned should give a hand.

The role already played by UNEP in support of MAB has already been significant, particularly for the regional

activities which are undertaken.

But ultimately the key to the whole operation probably lies in the hands of scientists from the industrialised countries. For them, the programme offers access to areas of the world in which challenging research projects are being developed, either through direct co-operation between MAB National Committees or through multilateral channels. It offers also the interest of adapting to new interdisciplinary methods and to a spectrum of research, the social value of which is beyond question.

Times are difficult everywhere for research funding, but the case for an environmental research programme such as MAB is unanswerable. The scientific community could, if it so wished, demand and obtain the necessary facilities which it alone can mobilise and utilise to make MAB a true and lasting success. □

international news

PRIME Minister Pierre Trudeau has defended Canada's sales of CANDU nuclear reactors to developing countries on the grounds that she cannot withhold from them the advantages of nuclear technology. In an address to the annual meeting of the Canadian Nuclear Association (CNA), he said: "We are a society which has not forgotten its frontier origins. We are a people who have experienced the torment of need, who understand the benefits of sharing. It is inconsistent with that experience and that understanding that we should now deny to the less developed countries of the world the opportunity to gain a handhold on the technological age . . .

"Surely, if we are ever to eliminate the immense disparities which now separate the living standards of rich and poor, it will be necessary to make available to the disadvantaged every technique at our disposal."

It would be unconscionable to deny to the developing countries the most modern of technologies as assistance in their quest for higher living standards, the Prime Minister said. "But in a world increasingly concerned about depleting reserves of fossil fuels, about food shortages, and about the need to reduce illness, it would be irresponsible as well to withhold the advantages of the nuclear age—of power reactors, agricultural isotopes, cobalt beam therapy units."

As a result of the explosion by India of an underground nuclear device last year, which was made with material from a reactor supplied by Canada, the Canadian government has come under criticism from both within the country and without. Critics have suggested that such an event should have been foreseen by Canada, and prevented.

Since the Indian explosion, the federal Cabinet has done some soul-searching and has tightened its nuclear safeguards policy—but it has also confirmed Canada's intention to go on selling nuclear reactors abroad. This decision, too, has drawn criticism.

In an obvious reference to such criticism, Mr Trudeau said: "We can be proud, as Canadians, of our cooperation with India. The decision taken by Prime Minister St Laurent to enter a nuclear assistance programme with India was a far-sighted and generous act of statesmanship."

Nuclear 'transfers' should always be

Canada answers her nuclear critics

from David Spurgeon, Ottawa

subject to safeguards, however, said the Prime Minister. Canada has now raised the standards of her safeguards "to the point that they are the toughest in the world [and] we refuse to engage in nuclear cooperation without an explicit exclusion of explosive uses."

Mr Trudeau said he did not pretend that the present system of inspection and detection of nuclear cheating was foolproof, and he was "painfully aware that the NPT [Non-Proliferation Treaty] is yet far from universally supported." But he reminded critics that the statute of the International Atomic Energy Agency (of which Canada is a member) charges the agency to spread peaceful applications of nuclear energy throughout the world, "bearing in mind the special needs of the under-developed areas."

(The latest element of the Canadian safeguards policy was announced May 4, 1975, by the Secretary of State for External Affairs at the NPT review Conference in Geneva. It provides that future Canadian bilateral nuclear commitments will be undertaken solely with countries that are parties to the NPT. Also, ratification of the treaty will be an important factor in Canada's decisions on provision of government financing in the nuclear field.)

The existence of some adverse public opinion concerning nuclear matters in Canada was acknowledged at the conference at which the Prime Minister spoke. The CNA's public relations committee said in its report:

"A number of new groups opposed to nuclear power developments have formed in Canada in the past year and there have been modest attempts to form a federation of such groups across the country, which suggests a new phase in the industry's relations with the public may be beginning."

The association's President, J. M. Douglas, President of Babcock and Wilcox Canada Limited, said that although the Canadian government and nuclear industry believe the CANDU system can give great benefit to

Canada through domestic and export markets, "if the opinion of a good majority of Canadians is not in accord with that of government and the utilities, our country's position with regard to the generation of electrical power in a few years' time could be put in jeopardy—as is happening in some other countries."

This seems to be happening because positive, factual information has not been made available in a clearly understood form, Mr Douglas said. "Small, but well organised, environmental groups have used information which is incomplete or inaccurate or misleading, to produce scare stories."

Too often this information—in the absence of factual information supplied from an informed source—has influenced fair-minded people against nuclear power, he said. "We must not let this happen in Canada. And it could. We must greatly increase our efforts to communicate factual information to those who seek it . . ."

Plans already have been made to do this, with a seminar to assist member organisations to communicate with various publics, and a new booklet.

In a review paper, J. S. Foster, President of Atomic Energy of Canada Limited (AECL) said Canada today has 2,500 MWe of nuclear electric generating capacity in operation and a further 6,000 MWe under construction. An additional 7,000 MWe is either committed or at an advanced stage of planning. By the end of the century there will be about 130,000 MWe produced by nuclear plants in Canada.

● L. J. Schofield, of the CNA's Economic Development Committee, says that there is a significant advantage for nuclear power generation in Canada if coal prices escalate at 8% or more a year; such rises would be offset only by sustained capital cost escalation rates in excess of 13% a year. At low coal price escalation rates of 5%, however, the competitive advantage of CANDU stations is small, and could be completely offset by double-digit inflation of capital costs.

"Double-digit inflation," says Schofield, "is a factor to be reckoned with today by the Canadian nuclear industry . . . If the costs of fossil and nuclear stations inflate at equal rates, then the advantage of nuclear generation due to lower fuel costs could be progressively offset by the increasing differential in capital cost." ☐

Soviet meetings, great and small

from Vera Rich

ONE of the most striking features of Soviet science is the large number of scientific conferences to which it gives rise. Leaving aside, at the one end of the scale, the major conferences of international bodies which happen to have chosen a venue in the Soviet Union and, at the other, small and relatively local gatherings, there still remain 25–30 All-Union meetings, conferences, symposia, and seminars which take place each week. In all, some 1,400 such conferences are scheduled for 1975, with an estimated attendance of some 210,000 scientists and technologists.

Although such conferences are conventionally hymned by Soviet planners as forming one of the most fruitful means of implementing the results of basic research in the national economy and of promoting interdisciplinary studies, in reality not all is well with the Soviet conference scene. According to a recent *Pravda* editorial, many conferences are becoming afflicted with the disease of "gigantomania". With several thousand scheduled speakers, a situation is reached where, even with drastic subdivision into different working groups (which, to a large extent, limits interdisciplinary contacts to outside the lecture hall), each lecturer is allotted only a few minutes in which to deliver only an abstract of his paper. This would be slightly less serious if the audience had already read it in preprint form, so that the short time available could be devoted to questions. But this, too, is not possible—gigantomania besets the preprints too. At the Fourth All-Union Seminar on "Methods and instruments for measuring discharges and quantities of gas" only one-fifth of the papers were ready in preprint form. The post-conference publication of proceedings is likewise extremely tardy so that the papers have lost much of their value before they ever appear in print. This problem, of course, is not peculiar to the Soviet Union—in few other countries, however, would it be considered so urgent as to merit editorial coment in the country's leading newspaper, recommending that steps should be taken to rectify the situation by all the bodies responsible, from the Academy of Sciences and the relevant ministries downwards.

● The overlap between the two forms of Soviet scientific meetings—the vast gigantomaniac official gathering and the small illicit gathering of refusniks —sometimes approach each other in a manner somewhat perturbing to the

authorities. This, according to his sons, is one of the main reasons why Academician Veniamin Levich has received such opposition to his desire to emigrate to Israel. So far, he is the only Member of the Academy of Sciences to request a visa (Professor Tumermann was, at the time he applied for a visa working at the Lebedev Physics Institute of the Academy but

Academician Levich: promised a visa.

was not himself an Academician). Levich who has long since been dismissed from his post still remains a member of the Academy, and, technically speaking, still retains the right to attend meetings. Although Levich's works are no longer mentioned by establishment Soviet scientists, and references to them in incoming Western works are blotted out by the censor, the authorities seem to prefer to let him remain an Academician, rather than put into action the complex machinary of expulsion, which could well bring a backlash of unfavourable publicity. Academician Levich has been promised his exit visa—"by the end of 1975". With the 250th anniversary celebrations of the Academy scheduled for October, it will be interesting to see whether Academician Levich will receive his visa before that date—or if not, whether he will assert his right to participate in the jubilee meeting.

● Another interesting problem is that of refusnik scientists invited to take part in international conferences to be held within the Soviet Union. The case of cyberneticists Aleksandr Lerner and Evei Gel'man is likely to provoke a problem for the Soviet authorities.

Lerner and Gel'man have been invited by the international organising committee to take part in the Conference on Artificial Intelligence to be held in Tbilisi this September. Judging from the case of Zhores Medvedev, who was forcibly prevented from attending the Kiev Conference on genetics, it seems unlikely that Lerner and Gel'man will be permitted to attend the Tbilisi Conference. How the problem will be resolved is still a matter for speculation, but latest reports indicate that Gel'man has been promised an exit visa, although he has not, to date, actually received it. To send both of them abroad before the Conference would certainly prove the happiest solution for the two refusniks themselves, and could well be the easiest way out for the Soviet authorities of what might otherwise prove an embarrassing and publicity provoking situation.

● A conference liable to cause a certain unease to the Soviet authorities was that of the Royal College of Psychiatrists, which held its annual meeting in London last week. The meeting unanimously confirmed a decision to send a telegram of protest to Professor A. V. Snezhnevskii, President of the Institute of Psychiatry of the USSR, deploring the misuse of psychiatry as a means of political repression. The telegram, signed by Sir Martin Roth, president of the college, cites specifically, "the continued incarceratian of Gluzman, Bukovskii and Blyushch, which appears a perversion of psychiatric practice and the denial of natural justice".

The case of Dr Gluzman, whose incarceration in a mental hospital seems to have been the direct result of his preparation of a report on psychiatric malpractice in the case of General Grigorenko, was raised at last year's Annual Meeting. Since then Sir Martin Roth has sent two letters to Professor Snezhnevskii on Gluzman's behalf, the first of which received an extremely unsatisfactory answer, stating that the case against Dr Gluzman contained no references to the Grigorenko affair. The second letter, which in effect was an enquiry as to what then were the charges against him, received no answer.

The telegram of protest also cites the case of Vladimir Bukovskii, co-author with Dr Gluzman of the famous *samizdat* "Manual of Psychiatry for Dissidents" (a guide to what to do if accused of mental illness as a result of one's political views) and Leonid Plyushch, the Ukrainian mathematical, who, as a result of the "treatment" he has undergone since hospitalisation for dissidence is now, according to the latest report (from an informant who saw him last April) in a state of virtual

catatonia with probably irreversible mental damage.

In addition to the protest to Professor Snezhnevskii, the meeting also resolved to send a telegram to Dr Gluzman himself—the first time that this particular form of protest has ever been undertaken by the college.

Among those who spoke in favour of this action was Dr Denis Leigh, Secretary General of the World Psychiatric Association, who said that in his view the type of action envisaged by the college was welcome and much to be encouraged. □

Oxford man wins large prize

PROFESSOR X has won for Dr Y from Oxford (who prefers to remain anonymous) a year's free subscription to *Nature*. Professor X is on 12 editorial boards and easily heads the list in *Nature's* competition (May 8); the runner-up could muster a mere nine appearances. □

THE effects of inflation on the prices of technical and scientific books are illustrated in this table of findings from a British survey. Eleven publishers submitted information for the survey, which was carried out by the Technical and Scientific Group of the Publishers Association Each was asked to give the extent and price, on publication, of their new scientific and technical books (and new editions) published in the years 1972, 1973 and 1974. Where there were two editions (eg, cased and paper) the cheaper was taken. In the case of 1974 they were asked to distinguish between publication in the first and second halves of the year. They were also asked to assign each book to a category, namely: A: books intended for purchase by undergraduate students; B: books intended for purchase by senior students, lecturers, practitioners, libraries, etc; C: books for which only a library sale is expected. The most rapidly rising cost was that of paper.

Year	Size of Sample	Total no. of pages	Total price (£)	Price/ 100pp (£)	% above 1972	
1972	157	44462	381.75	0.86	—	
1973	140	39062	390.15	1.00	16.2	Category A
1974(1)	74	21343	218.25	1.02	18.6	
1974(2)	49	12029	138.75	1.15	33.7	
1972	100	29297	457.95	1.56	—

correspondence

Deep in Egypt

SIR,—Having carried out surveys during and after the Second World War in Libya, Egypt and the Sudan, I was very interested to read the article (June 19) on the project for producing power by diverting Mediterranean water into the Qattara Depression by a canal through the Alamein area. Your correspondent was incorrect, however, in ascribing the initial surveys and ideas for this project to Professor Bassler, an ex-officer of Rommel's army; it is much older than that. In fact it dates back to the previous war, since it was in 1917 that Dr John Ball, the Director of the Egyptian Desert Survey, lent a small aneroid barometer to the officer in charge of a British Light Car Patrol who was going to travel in the area. The officer came back without the aneroid but with a reading for the Qattara Spring of some 60 metres below sea level—and presumably with a somewhat tarnished reputation as a surveyor!

Dr Ball did not, however, forget this odd result; and in 1926 he was able to send a professional surveyor, G. F. Walpole, to make a more detailed investigation, which revealed for the first time the full extent and depth of this remarkable feature. Describing this and other investigations in 1927 in the *Geographical Journal*, Dr Ball then suggested that the depression might be used as a source of power by diverting Mediterranean water into it through tunnels. Six years later, when a complete topographical and geological survey had been made, he published a long paper in the same journal, giving detailed estimates of the sizes of tunnels required, the energy available and the length of time (several hundred years) that the project could last. Clearly the rate at which salt will accumulate even from sea water is very much slower than the rising tide of silt in the upper reaches of Lake Nasser, even though with modern engineering techniques much larger channels or tunnels can be envisaged.

Dr Ball, like Dr H. E. Hurst who organised the comprehensive collection of data about the Nile Basin on which so many projects were based, belonged to a small band of British surveyors and scientists who worked for many years in Egypt in the early years of this century. With the wisdom gained from long experience in the area added to their native wit and scientific training, they wrote a number of far-sighted papers which those who are now suggesting new versions of their projects will do well to study.

Yours faithfully,
JOHN WRIGHT
Effingham, Surrey

English and editorial boards

SIR,—Mr Andrewes describes himself as a hack. Nothing in the wording of his letter (July 10) suggests that the epithet is justified, but there are many people around editorial offices to whom it is applicable. Instead of confining themselves to turning poor into passable English, they seem to delight in trying to turn straightforward English into jargon. In a proof that came last week an editor was trying to get me pompously to refer to myself as 'the author'. Proofs of two papers sent to a microbiological journal a few years ago had been so mangled that I withdrew them and published them as originally written in *Proc. R. Soc.* **B.** A friend had a recent paper to a nutritional journal turned in places into germanic near gibberish. And so it goes on, making people who recognise clear English think that all scientists write badly.

If a paper comes within the province of a journal and seems to be scientifically acceptable, an editor's job is the elimination of ambiguity and prolixity. These are matters of fact. An editor can say: "This phrase could mean A or B. Which do you mean?" or "This amounts to so-and-so, which is only half as long as the original." It is no part of an·editor's job to insert misconceptions about the English language, however sincerely felt, into someone else's paper.

Yours faithfully,
N. W. PIRIE
Harpenden, Herts,

Fostering spin-off

SIR,—It was with much interest that I read the recent paper by Isaacs *et al.* (January 24) on cyclogenesis by motor vehicle movements. I wonder how many people outside Australia are aware that the Aborigines have been making use of this principle for centuries. Why else would their rain making dances consist of a steady clockwise progression?

Related to this, I am at present working on a theory that the drying up of central Australia followed the invention of the boomerang, whose anticlockwise rotation would inhibit cyclonic activity. As happens with most revolutionary ideas, however, I have been having trouble funding this programme.

Yours faithfully,
K. H. LLOYD
Salisbury Heights, South Australia.
Darwin's cancer research

SIR,—In considering the scope of subject matter relevant to the study of cancer, Stoker (April 17) suggests that much of cell-oriented biology may have such implications. It may, but it would be shortsighted to stop there. Natural selection has obvious relevance, at least obvious to an evolutionary biologist, and Cairns (May 15) has discussed this explicitly. It has also become central to immunology. My only contribution to oncology came as a direct result of work in palaeoecology. Theoretical frameworks that develop in one subject often have application elsewhere, and this really cannot be foreseen. Would

the Imperial Cancer Research Fund have supported Darwin?

Yours faithfully,
LEIGH VAN VALEN
University of Chicago,
Chicago, Ill. 60637

Integrity in science

SIR,—I am sorry that the only comment accompanying my letter (June 12) mainly concerns its occasion and not its essence. I would gladly ignore it, but the claims of truth preclude that luxury.

Mr. Maddox's suggestion that the non-appearance of his leader resulted from the "offensiveness and repugnancy" of the correspondence is false. The article was promised, "before the end of the year", on November 24, 1969. Successive (polite) enquiries from Lord Soper and me brought such replies as "the article is now almost ready" (January 21, 1970); it would be delayed "a week or two" (end of March 1970); until Lord Soper's final inquiry (July 6, 1970) brought no reply—or the article. It had been promised in place of my reply to Professor Synge who had written (*Nature*, **219**, 790; 1968) that "as the result of a lengthy correspondence with Professor Dingle" he and I had agreed that either "the concepts used in the special theory of relativity as ordinarily understood" or "the concept of clocks that run regularly, as understood by Professor Dingle" must be abandoned. Since my concept of such clocks has never been represented as other than an instrument so recognised by a standard observatory, the only relevant property I required being an inability of one to run concurrently both faster and slower than another, it was now clearly mate in one move. Maddox made·that move impossible by steadfastly suppressing my rejoinder; it has never appeared. (Incidentally, his statement now that I have "shifted my ground" since 1968 is here seen clearly to be false: Synge's diagnosis is identical with my position as stated in my recent letter).

Maddox should have quoted more of my letter of April 6, 1971; it ran: "In view of the failure of all other means of getting a straightforward answer to my criticism of special relativity . . . I have been, with great reluctance, forced to the extreme measure of writing a book describing the course of the whole series of evasions . . . I write this final letter, which will be included in the book if necessary, to invite you to give your own explanation of your attitude, which I promise to include verbatim. I repeat what I have said before—that my sole object is to get this matter settled, first of all with absolute openness ·and avoidance of all further evasion and quibbling, and secondly,

provided that that is done, with the minimum of sensation and unpleasantness. Action on your part, even now, would make a full exposure of the ethical aspect of the matter unnecessary" Your readers can judge whether the "offensiveness and repugnancy" of this letter adequately excuse the succession of broken promises a year earlier.

There was a sequel to "the recent incident" as related by Mr. Maddox. The author of the article mentioned subsequently asked for his side of the story (although, since it had already appeared in the Editorial, this might well seem redundant) and was given a vague statement that implied, if anything, that the "promises" ascribed to me had another source than that which he now owns, which was "even more full of somewhat unrealistic threats". I know of no letter which can be so interpreted. It was to prevent a recurrance of such misrepresentation and for that reason alone that I felt it necessary to record the actual facts.

I suppose I must reply once more to the charge that "Dingle's confusion stems from his assertion that special relativity requires that the differences of rate should 'actually and not merely apparently' occur. The truth, of course, is quite the opposite." Whenever the special relativity effects of motion are invoked to predict or explain something observable (for example, asymmetrical ageing, cosmic-ray behaviour . . .) they are held to be "actual", whenever this leads to a contradiction they become only "apparent"; and anyone to whom this is unacceptable is deceived by "commonsense". The letter I have called "L" completely refutes Maddox's statement. His technical example involving "lasers" and "algorithms" refers to a completely different phenomenon which has nothing at all to do with the matter.

I withhold comment on the rest of Maddox's letter, remembering what Shakespeare said about painting the lily, and leave your readers to judge whether Maddox is right in denying that there is "an ethical issue" here. I am sure, however, that the many who agree with me that there is, will require a plain, direct answer to my question if they are to retain their trust in the integrity for which the scientific world has in the past been justly noted. I most earnestly hope that among those with authority and responsibility in this matter, there will not be wanting someone ready to have done with "doublethinking", to clear his mind and words of cant, and to exhibit the candour and courage needed to provide such an answer.

Yours faithfully,
HERBERT DINGLE
Purley, Surrey

news and views

Applying molecular genetics to a human disease

from Edward J. Benz and David G. Nathan

THE α- and β-thalassaemia syndromes are a heterogeneous group of inherited haemoglobinopathies characterised by reduced or absent synthesis of structurally normal α or β globin chains. The first step to identifying the nature of the syndromes was made in 1971 when the *in vivo* defect in chain synthesis was reproduced *in vitro* using β-thalassaemia globin mRNA (Nienhuis and Anderson, *J. clin. Invest.*, **50**, 2458; Benz and Forget, *J. clin. Invest.*, **50**, 2755). Then a quantitative deficiency in globin mRNA was demonstrated by the technique of hybridising thalassaemic globin mRNA with radioactive DNA complementary to globin mRNA (Housman *et al., Proc. natn. Acad. Sci. U.S.A.*, **70**, 1809; 1973; Kacian *et al., Proc. natn. Acad. Sci. U.S.A.*, **70**, 1886; 1973). Total absence of cytoplasmic β chain mRNA in homozygous β^0-thalassaemia (Forget *et al., Nature*, **247**, 379; 1974; Benz *et al., Blood*, **45**, 1; 1975) and α-chain mRNA in homozygous α^0-thalassaemia (Kan *et al., J. clin. Invest.*, **53**, 37a; 1974) has subsequently been demonstrated both by translation in cell-free systems and by complementary (c) DNA–mRNA hybridisation.

It is, therefore, now clear that the primary genetic lesion in thalassaemia is a defect in the synthesis, processing, transport, or stability of the α chain mRNA (in α-thalassaemia) or β-chain mRNA (in β-thalassaemia). Since total absence of mRNA in the α^0- or β^0-thalassaemias suggests gene deletion, investigators are now concentrating on the regulation of human globin gene expression. These disorders thus continue to be the examples *par excellence* of human diseases to which the techniques and concepts of molecular biology can fruitfully be applied.

Ottolenghi *et al., (Nature*, **251**, 389; 1974) and Taylor *et al., (Nature*, **251**, 392; 1974) recently isolated total cellular DNA from livers of infants with Hb Bart's hydrops foetalis, the homozygous form of α^0-thalassaemia. This DNA hybridised to purified β-chain cDNA as efficiently as normal DNA but failed to form any double stranded hybrids with α-chain cDNA. This constitutes strong evidence that these infants had no α chain genes

and that, therefore, the α^0-thalassaemia allele is a gene deletion.

Kan *et al. (Nature*, **255**, 255; 1975) have now applied the same approach to answer a more vexing question: the number of α chain genes present in normal man. There has been considerable controversy over whether the haploid number of chromosomes contains a single α chain gene or duplicated α chain genes (Lehmann and Carrell, *Br. Med. J.*, **4**, 748; 1968; Koler and Rigas, *Ann. hum. Genet.*, **25**, 95; 1961; Hollan *et al., Nature*, **235**, 47, 1972; Abramson *et al., Science*, **169**, 194; 1970; Milner *et al., Lancet*, i, 729; 1971). The two hypotheses make very different predictions about the genetic basis of the four classical α-thalassaemia syndromes described in the Asian populations among whom α-thalassaemia is most common. These syndromes include an asymptomatic silent carrier state (α-thalassaemia$_2$ trait), a mild hypochromic anaemia (α-thalassaemia$_1$ trait), a moderately severe haemolytic anaemia (Hb H disease), and fatal hydrops foetalis; the deficits in α chain synthesis in each syndrome correspond well to the clinical severity of each disorder. The 'one gene' theory postulates the existence of two forms of α-thalassaemia gene: a 'mild' (α^+-thalassaemia) allele, and a 'severe' (α^0-thalassaemia) allele heritable at a single locus. The four syndromes would then result from various combinations of normal, α^+, and α^0 alleles in the diploid state. The two-gene theory postulates that all α-thalassaemia alleles are α^0-thalassaemia alleles. In increasing order of severity, the four syndromes would then result from inheritance of α^0-thalassaemia alleles at one, two, three or all four of the α chain loci available in a diploid cell containing duplicated α-chain genes.

Since all α chain genes are deleted in hydrops foetalis, the α^0-thalassaemia allele can be regarded as a gene deletion regardless of which model, one gene or two gene theory, is correct. But the one-gene model predicts that a patient with Hb H disease (α^+-thal/α^0-thal) would have half the normal number of α chain genes. The two-gene model for Hb H disease (α^0-thal-α^0-thal/α^0-thal-α) predicts that this

patient would have only one quarter the normal number of α-chain genes.

Kan *et al.* have now compared the different rates at which DNA from normal and Hb H disease patients hybridises to fixed amounts of α chain cDNA. This method of kinetic analysis depends on the fact that formation of double-stranded hybrids between a fixed-amount cDNA base sequence and a homologous base sequence in cellular DNA will depend on the concentration of the cellular DNA sequence (in this case, an α-chain gene) and time. By measuring the percentage of the cDNA input bound into hybrids at various times, one can construct a 'C_0t' curve (C_0t=initial concentration of cellular α chain DNA sequences $\times$ time of reaction); plots of percentage hybridisation against the C_0t values at each time point permit comparison of the relative rates at which cellular DNA from each type of patient hybridises to the α chain cDNA. The $C_0t_{1/2}$ (C_0t value at which 50% hybridisation occurs) of each curve then serves as a measure of the α chain gene content of one DNA sample relative to the others. When these investigators compared normal DNA to Hb H disease DNA, the $C_0t_{1/2}$ for the Hb H sample was roughly four times as high as that for the normal sample implying that the Hb H sample had only one quarter the normal complement of α chain genes.

These data seem to provide direct biochemical evidence supporting the two-gene theory for α-thalassaemia and the existence of duplicated α chain alleles in normal man. But the use of C_0t curve analysis is fraught with technical difficulties when applied to the analysis of genes present in one or only a small number of copies in human DNA. The α chain genes account for only 10^{-7}–10^{-8} of the total base sequences present in the human genome. Hybridisation between α-chain cDNA and these α chain genes thus occurs very slowly, necessitating the plotting of the C_0t values on a logarithmic scale. Two- to four-fold differences are relatively difficult to measure from the plotted curves. Kan *et al.* devised a set of experiments to determine whether their method could accurately

define this range of differences in $C_o t_{1/2}$. By mixing hydrops foetalis DNA (no α chain genes) with normal DNA in known proportions, they created artificial mixtures having a quarter and half the normal concentration of α chain sequences. The quarter mixture gave $C_o t_{1/2}$ values with α chain cDNA identical to those obtained with Hb H disease DNA. These results support the technical validity of the $C_o t_{1/2}$ values measured for the Hb H DNA samples.

The application of the same approach to β^0-thalassaemia would seem to be straightforward. Unfortunately, the δ chain of Hb A_2 ($\alpha_2\delta_2$) is structurally very similar to the β chain (only 10/146 amino acid differences). Forget *et al.* (*Nature*, **247**, 379; 1974) have shown that β chain cDNA cross-hybridises with δ chain mRNA, suggesting close homology between the mRNAs coding for δ and β chains. If the β chain genes were deleted in homozygous β^0-thalassaemia, DNA from such a patient would have half the normal number of 'β-like' DNA sequences ($\beta+\delta$ genes) since each gene appears (from family studies) to be present as only a single copy. This difference, as shown by Kan *et al.* for their DNA mixtures, comes close to the limits of reproducibility. Homozygous $(\delta\beta)^0$-thalassaemia has been described but this condition is exceedingly rare

and DNA from these patients has not yet been available for analysis. Ottolenghi *et al.* (*Proc. natn. Acad. Sci. U S.A.*, **72**, 2294, 1975) have analysed DNA from a patient doubly heterozygous for β^0-thalassaemia and $(\delta\beta)^0$-thalassaemia in whom none, one, two, or three of the four relevant loci could be deleted, depending on whether either or both types of thalassaemia involved gene deletion. Their results showed a definite difference between this patient's DNA and normal DNA but did not clearly distinguish among the various possibilities.

Further clarification of the genetic composition of patients with β^0-thalassaemia will probably occur only when DNA from individuals with homozygous $(\delta\beta)^0$-thalassaemia can be obtained, or when the content of human globin sequences can be amplified by integration of human globin DNA into bacterial plasmids. The recent progress achieved with α^0-thalassaemia, however, is encouraging. The molecular basis of these disorders appears to be understandable in terms of the number of α chain loci deleted from the genome Perhaps more importantly, the investigation of these syndromes has shown that the same techniques can be applied to resolve issues relating to the number, content, and organisation of globin genes in the normal individual.

actions in free space, on the other hand, must conserve energy and momentum exactly so that they are on the energy shell. A phenomenological nucleon–nucleon potential fitted to the two-nucleon data does not necessarily have the correct off-energy-shell behaviour, and so may not be correct for calculating interactions inside the nucleus when other nucleons are present.

Third, the purely mathematical difficulties involved in calculating the properties of a many-body system from a knowledge of the two-body interaction are so severe that only approximate results can be obtained for any but the simplest system or the simplest nuclear property. It is for this reason that the most important information is obtained from studies of the two bound three-nucleon systems, the helion and the triton. Here it is possible to obtain quite accurate results using a variational calculation or by the methods of Faddeev.

Finally, there is a difficulty in principle that would still remain even if we had a complete knowledge of the nucleon–nucleon interaction and could overcome the difficulties of calculating from it the properties of many-body systems. This is that there may be forces that only come into play in the presence of three or more nucleons. By definition we can never find out anything about these forces by studying the interactions of two nucleons. Indeed, assuming that we can overcome the other difficuties, we can obtain some indication of the importance of three-body forces by seeing how well we can calculate the properties of a three-nucleon system using only two-body forces. If there is a discrepancy, indicating the presence of three-body forces, a three-body force can be included in the interaction and the calculation repeated to see if this gives agreement with the data.

Such three-body forces can be chosen phenomenologically, but here the difficulty is that there are many possible forms, for example $V_3 f(r_{12}+r_{13}+r_{23})$ or $V_3 f(r_{12} r_{13} r_{12})$, where r_{12} is the distance between particles 1 and 2 and so on, and it is not clear what is the best form to take. An alternative approach is to try to calculate the three-body force from meson theory, and use this in calculations of nuclear structure.

In the last few years there have been several sophisticated calculations of the properties of the triton using the best phenomenological potentials fitted to the two-nucleon data, and it has been found that they all give a binding energy that is lower than the experimental value by one or two MeV. Additional calculations show that the binding energy can be varied by as much as 3 MeV by altering the

Nuclear three-body forces

from P. E. Hodgson

ONE of the main aims of nuclear physics is to understand the structure of nuclei in terms of the interactions between the constituent nucleons. The nucleon–nucleon interaction may be studied by measuring the cross sections, polarisations and other characteristics of the scattering of free nucleons, in particular proton–proton and proton–neutron scattering. (It is not practicable to measure neutron–neutron scattering directly since suitable targets cannot be made.) Additional information is obtainable from studies of the only bound two-nucleon system, the deuteron. Very many studies of the nucleon–nucleon interaction have been made over the years in these ways, and the results can be represented by a phenomenological potential that depends on the distance between the two nucleons and on their spins. These potentials cannot be deduced from the experimental results; instead a trial form of the potential is postulated using forms suggested by meson theory and its parameters are adjusted to give the best fit to the data. The potential is thus not unique, and in fact several potentials have been found that give a good overall fit to the data on the

interaction of two nucleons.

The next stage is to use this potential to calculate the properties of nuclei consisting of three or four nucleons, and to see how well the results agree with measurements on the nuclei themselves. There are several difficulties in carrying out this programme. First our knowledge of the nucleon–nucleon interaction is incomplete and subject to ambiguities. This is not too serious since it is possible to compare the results obtained by using different nucleon–nucleon interactions and if they are essentially the same it is reasonable to assume that the differences between the interactions are not important for the nuclear property under consideration.

Second, in a many-body system a nucleon–nucleon interaction takes place in the field of other nucleons, which can absorb momentum. A collision can than occur in which energy is not conserved by an amount ΔE, provided it takes place in a time Δt related to the energy uncertainty by $\Delta E \Delta t < h$. This is expressed by saying that nucleon–nucleon interactions inside the nucleus can take place 'off the energy shell'. Nucleon–nucleon inter-

off-energy-shell behaviour, but if this is done so as to give the correct binding energy the charge distribution no longer agrees with that found from electron elastic scattering. On the other hand if the off-energy-shell behaviour is adjusted to give correct charge distribution the binding energy becomes unacceptably low. It is thus not possible to obtain a simultaneous fit to the binding energy and the charge distribution by varying the off-energy-shell behaviour.

These calculations therefore suggest that possibly the three-body forces contribute significantly to the structure of the triton, and recently Yang (*Phys. Rev.*, **C10**, 2067; 1974) has made a detailed calculation from meson theory to investigate this. He took into account the emission and absorption of pions to lowest order as well as exchange of a ρ meson with a pion and the scattering of a nucleon into an N* excited state at 1,236 MeV. He then evaluated the contribution of the resulting three-body potential to the binding energy of the triton using a variational triton wave function and found that it gives an important contribution of 2.32 MeV to the bonding energy. This is indeed more than enough to bind the triton, the excess being about 0.3 to 0.8 MeV, but it is likely that this is due to higher-order processes not taken into account by Yang.

These calculations suggest that the major part of the discrepancy in the calculated binding energy of the triton can be accounted for by taking three-body forces into account. Furthermore, the contribution of the three-body forces is appreciable, amounting to about a third of the total binding energy. This conclusion is highly unwelcome, since it suggests that the three-body forces, which are complicated and difficult to handle, are likely to be important in a wide range of nuclear structure calculations.

The current work on proton knockout reactions can also give information on the importance of three-body forces. Koltun and others have shown that if only two-body forces operate the total energy of the nucleus may be expressed as a sum of the nucleon removal and kinetic energies over all the occupied orbits. A recent analysis of experimental data for the (e,e'p) reaction on ^{12}C at 497 MeV (*Nature*, **250**, 105; 1975) showed that for protons this sum rule gives −4.0±0 5 MeV for the mean binding energy per proton compared with the accurate value of −6.93 MeV obtained from the nuclear masses with Coulomb corrections. One possible explanation is that there are some fragments of the single-particle strength so far away from the main peak that they escape detection, so that the real

centroid energy is appreciably different from the apparent centroid energy. Another explanation is that three-body forces, which were not taken into account in the derivation of the sum rule, are indeed important. A rough estimate however indicated that the contribution of the three-body forces is small, so it was concluded that the former explanation is the correct one. The results of Yang now make it likely that three-body forces must be taken into account in the derivation of the sum rule.

Another indication of the importance of three-body forces comes from the calculations of Blatt and McKellar (*Phys. Lett.*, **52B**, 10; 1974) They studied the contribution of three-body forces to the binding energy of nuclear matter, and found that it is enhanced if the nucleon–nucleon correlations are taken into account. In this calculation

they used the correlation function derived from the Reid soft core potential, that has been obtained by systematically fitting a large body of data on nucleon–nucleon interactions. Their most surprising result is that the two-pion exchange three-body forces contribute as much as 6 MeV to the binding energy of nuclear matter. This result shows that the Reid potential overbinds nuclear matter when three-body forces are included. Since higher order three-body force terms and four-body force terms are likely to be negligible this indicates that the Reid potential needs to be modified to bring it into accord with all the data.

All these calculations indicate that it is not justified to neglect the contributions of three-body forces, and that they will now have to be taken into account in many nuclear reaction and nuclear structure calculations.

Deterministic models with chaotic dynamics

from Robert M. May

IN nature there are many situations where population growth is a seasonal thing, with no overlap between generations. For instance, many temperate zone insects produce one short-lived adult generation each year, and the population trajectory consists of a sequence of discrete points. Periodical cicadas, with 7, 13 or 17 year intervals between generations, are an extreme example. In mathematical models for such systems, time is a discrete rather than a continuous variable, and one has difference equations rather than differential equations: the population at generation $t+1$, N_{t+1}, is related to that at t, N_t, by some equation of the form

$$N_{t+1} = F(N_t) \qquad (1)$$

Li and Yorke (*Am. Math. Monthly*, in the press) have recently proved a remarkable theorem about any such difference equation. If there is a three-point cycle (that is, a solution such that $N_{t+3} = N_t \neq N_{t+1} \neq N_{t+2}$), it necessarily follows that for the same parameter values there are cycles of every integer period, and furthermore there exist an uncountable number of initial points for which the system is not even asymptotically periodic! Li and Yorke aptly entitle their paper "Period Three Implies Chaos".

Specifically, consider the equation

$$N_{t+1} = \lambda N_t \exp (- a N_t) \qquad (2)$$

This describes a population which at low densities grows by the multiplicative

factor λ ($\lambda > 1$), but at high densities has a propensity to population decrease (the exponential form being plausible if epidemics tend to sweep the population at high densities). This equation has arisen as a model for fish (Ricker, *J. Fish. Res. Bd. Can.*, **11**, 559–623; 1954), periodical cicadas (Lloyd et al., unpublished), and insect populations in general (Moran, *Biometrics*, **6**, 250–258; 1950; Cook, *Nature*, **207**, 316; 1965). The full complexity of its dynamical behaviour has, however, only recently been laid bare (May, *Science*, **186**, 645–647; 1974). For $7.34 > \lambda > 0$, the population is stable about a constant equilibrium value, to which it will tend to return if perturbed. Beyond $\lambda = 7.34$, this stable point bifurcates, and the population alternates up and down in a stable two-point cycle; this two-point cycle in turn becomes unstable, giving way to a stable four-point cycle, then an eight-point cycle, and so on; eventually the range $14.77 > \lambda > 7.34$ is filled by a hierarchy of stable cycles of periods 2^n. For $\lambda > \lambda_c = 14.77$ a chaotic regime is entered: for any given value of λ there is an infinite number of different periodic trajectories, along with an uncountable number of initial points for which the system never settles into any cycle. Further into this chaotic region, for $\lambda > 22.25$, there is a three-point cycle and consequently every integer period is represented.

At this point, proud owners of sophisticated pocket calculators may care to pause and verify some of these statements.

The above phenomena are not patho-

logical consequences of the particular equation (2), but are generic properties of any difference equation (1) describing a population with a propensity to grow at low densities, and to crash at high densities. Among many other examples which could be culled from the entomological literature is

$$N_{t+1} = a\,N_t - b\,N_t^2 \qquad (3)$$

This could be regarded as the simplest nonlinear difference equation (see, for example, Chaundy and Phillips, *Q. J. Math.*, **7**, 74–80; 1936). It has a spectrum of dynamical behaviour similar to equation (2), namely a stable point if $3 > a > 1$, stable cycles of period 2^n if $3.57 > a > 3$, chaos for $4 > a > 3.57$ (and here N tends to $-\infty$ for $a > 4$).

Practical questions aside, these equations have intrinsic mathematical interest in providing simple examples of multiple bifurcation processes. Other examples are much more recondite and intractable.

Another way of describing the chaotic regime is to observe that arbitrarily close initial population values can ·lead to population trajectories which, as time goes on, diverge widely. Even if we have a model which is very simple and fully deterministic, with all parameters assumed to be constant and exactly known, the future is unpredictable. As emphasised by Oster, the dynamics of the system are in many respects indistinguishable from the sample function of a random process, and are best described in stochastic terms.

At present, apparently random fluctuations in animal populations are attributed to environmental vagaries, or to sampling errors. It may be that in the real world the nonlinearities in population growth equations are not sufficiently severe to carry them into the chaotic regime, but the possibility at least deserves attention. Other areas in which similar difference equations have recently arisen are: epidemiology (Hoppensteadt, *CBMS Regional Conf. Ser. appl. Math.*, **20**, 1975); demography (for example, Lee, *Demography*, **11**, 563–585; 1974); macroeconomics (for example, in nonlinear generalisations of the Harrod–Domar model); genetics (Rocklin and Oster, *Am. Nat.*, in the press). In all these examples, the possible occurrence of chaotic solutions needs to be considered.

Chaotic dynamics arising from bifurcations in deterministic models have been noted in other situations. Thus Lorenz (*Tellus*, **16**, 1–11; 1964) has discussed a set of three coupled nonlinear differential equations as a very much oversimplified model of convection processes in the atmosphere, and has drawn from the ensuing chaotic ·solutions the moral that long-term weather forecasting may be infeasible even if one had a simple deterministic model. The details of the bifurcation process here are much more complicated than in simple equations such

as those above, and are still being unravelled (for example, McLaughlin and Martin, *Phys. Rev. Lett.*, **33**, 1189–1192; 1974). Likewise Ruelle and Takens (*Comm. Math. Phys.*, **20**, 167–192; 1971) have proposed a set of four deterministic coupled nonlinear differential equations, with a complex bifurcation structure, as a paradigm for the transition from laminar to turbulent fluid flow. And in an ecological context, Hassell and Comins (*Theor. Pop. Biol.*, in the press) have followed up the above work by exploring the way chaotic population dynamics arise somewhat more easily in discrete time models of two competitors, and Beddington, Free and Lawton (*Nature*, **255**, 58–60; 1975) have done a similar job for discrete time predator–prey models.

Apart from implications in specific scientific contexts, there are general morals to be drawn from the rich spectrum of dynamical behaviour of simple equations such as (2) and (3). Most students come away from elementary mathematics and physics courses (which emphasise linear models) with the impression that simple deterministic models have simple deterministic dynamics. This is, in my view, a very misguided prejudice to bring to biology, economics or sociology, where the simplest models are likely to be nonlinear, and consequently can have strange dynamics. Equation (3) could be studied by high school students before they met differential calculus: it would do them good.

I conclude with some cocktail party chit-chat. Note that the properties of equations such as (2) and (3) in the chaotic regime help to reconcile the Calvinist view of a foreordained, deterministic Universe with the appearance of free will in the world: the Calvinist God knows the exact initial conditions. Less flippantly, one may recall the objections to the probabilistic foundations of modern quantum mechanics, summarised by Einstein's objection: "God does not play dice". Many people have speculated that there may be 'hidden variables', and an underlying deterministic structure. Equations such as (2) and (3) can provide very simple examples of fully deterministic systems whose dynamics are best described probabilistically, and may go some little way toward adding substance to these speculations.

New confidence in ancient pollen data

from Peter D. Moore

THE pious hope of all who study past vegetation by the use of pollen analysis is that the abundance of the pollen of a particular taxon within a deposit bears a close relationship to the contemporary abundance of that taxon in the

vicinity of the deposit Yet, despite the palaeoecologist's declared belief that the present is the key to the past, the study of the relationship between modern pollen rain and the vegetation responsible for it has been sadly neglected. As a result, most of the vegetational interpretations appended to accounts of pollen stratigraphy are largely based upon glib and unjustified assumption.

But information on current pollen rain is now being collected, and many palynologists must have breathed sighs of relief when they saw data such as that published by Lichti-Federovich and Ritchie (*Rev. Palaeobot. Palynol.*, **7**, 297; 1968). These showed that surface sediment samples taken from the major vegetational zones of northern North America contained pollen which broadly corresponded in composition to the vegetation of those zones. Treeless tundra sites proved, predictably, an exception since long-distance transport, particularly of gymnosperm pollen, was a major component of the pollen rain.

Since that study, information on pollen rain has been collected elsewhere from a variety of vegetation types. Webb, for example (*Ecology*, **55**, 17;

1974) sampled the surface sediments of 64 lakes, evenly distributed over a study area in lower Michigan. He could draw fairly precise isofrequency contours of the major tree pollen types across lower Michigan and these corresponded reasonably well with relative abundance maps of the trees concerned. The exceptions were pine and poplar, which were respectively over- and under-represented in the surface sediments. The general north–south gradient in vegetation and in pollen spectra was confirmed by principal components analysis.

Information of this sort causes British palynologists to be filled with a new confidence in the usefulness of that painstakingly accumulated assemblage of fossil pollen data (now safely stored in the Quatenáry data bank at Cambridge). As a result some of these data have recently been dusted down and subjected to fresh scrutiny and analysis by Birks, Deacon and Peglar (*Proc. R. Soc. Lond,.* **B189**, 87; 1975). Basically they have attempted to reconstruct pollen rain maps of the British Isles of 5,000 years ago, using isofrequency contours based on the relative proportions of tree pollen in contemporary peats and lake sediments.

The choice of the period for study, around 3,000 b.c., is a consequence of the recent collation by Smith and Pilcher (*New Phytol.* **72**, 903; 1973) of radio-carbon dates from the major pollen stratigraphic horizons in Britain, which have been used as the basis for the Godwin zonation system. As expected, their collation served to demonstrate the metachroneity of these boundaries in different parts of the British Isles, with the notable exception of the elm decline horizon. This horizon (formerly used to demarcate Godwin's zone *VIIa* from zone *VIIb*— the 'Atlantic-Sub-Boreal transition') was generally dated at between 5,400 and 5,100 b.p. throughout most of the British Isles. It therefore provides a very useful datum horizon in pollen stratigraphic profiles, which is why Birks *et al.* have chosen the levels preceding the elm decline for their analysis.

One feature to emerge from their maps is the paucity of sites from which pollen data are available in the midlands and the south of England compared with the north, the west, and Ireland. This lack of sites means that the placing of isopollen contours in the midlands and south has to be somewhat arbitrary.

The overall picture conveyed by the maps is one of a vegetational gradient within the British Isles in which birch and pine are concentrated in northern and eastern Scotland (with an interesting 'island' of pine in East Anglia),

oak in northern England, elm and hazel in Ireland and the south-west, and lime in south-east Britain. This north-west–south-east gradient is confirmed by principal components analysis of the data; 54% of the total variance in the data is accounted for by the first three principal components, which reflect the major vegetational regions of the British Isles when plotted on a map. The remaining variance is presumably due to local site factors which produce heterogeneity within the regional gradient.

Although there is a greater abundance of data since Godwin (*New Phytol.*, **39**, 370; 1940) first performed this type of mapping exercise, the conclusions are very similar. What has changed is the confidence with which one can interpret these pollen maps of the period prior to the advent of Neolithic man.

Eukaryote transcription initiation sites

from Harry R. Matthews

THE control of gene expression in higher organisms remains a mystery in molecular terms. One of the stages at which control can be exercised is transcription of the gene (DNA sequence) into an RNA sequence which can then be processed and eventually translated. The cell controls transcription in two ways: it avoids transcribing DNA which has a function not expressed through transcription; and it concentrates transcription on those genes that are active or that are controlled at a later stage in expression

DNA is transcribed by an enzyme, DNA-dependent RNA polymerase. Higher organisms possess several such enzymes which are usually classified, operationally, on the basis of resistance to the drug, α-amanitin. Class A, or I, enzymes are resistant; class B, or II, enzymes are very sensitive; and class C enzymes are fairly sensitive. Class A enzymes transcribe the genes for ribosomal RNA and are located in the nucleolus; class B enzymes probably transcribe the bulk of the remaining expressed DNA; and class C enzymes may transcribe the reiterated genes for tRNA and 5S RNA. How does RNA polymerase B know which DNA sequences to transcribe? It seems unlikely that the enzyme itself is responsible for the entire range of tissue-specific transcription that can be observed by molecular hybridisation techniques since, for example, some tissue-specific transcription can be observed *in vitro* using chromatin from different mammalian tissues and bacterial RNA

polymerase. However, especially in the light of reports that a large proportion of DNA in chromatin is available for protein interactions, RNA polymerase B could well need a built-in specificity for particular initiation sites on DNA in order to limit the amount of DNA that needs to be covered by the tissue-specific control elements.

Evidence for such specificity is accumulating. Meilhac and Chambon (*Eur. J. Biochem.*, **35**, 454; 1973) and, now, Cedar (*J. molec. Biol.*, **95**, 257; 1975) have shown that there is a limited number of initiation sites for RNA polymerase B on homologous calf thymus template. Meilhac and Chambon allowed initiation to occur by incubating DNA and polymerase in the absence of nucleoside triphosphates, then adding the rifamycin derivative AF/013 which prevented further initiation and nucleoside triphosphates which permitted chain elongation. The number of RNA chains synthesised was determined from the incorporation of γ-^{32}P-purine triphosphates. They found, on average, one initiation site per 60.000 nucleotide pairs. Cedar has confirmed this result by using high salt conditions to prevent re-initiation of RNA chains after a pre-incubation in low salt, a method first used by Hyman and Davidson in a prokaryote system. He found one initiation per 30.000 nucleotide pairs. Cedar also counted his RNA chains by measuring ^{3}H-UTP incorporation and dividing by the RNA molecular weight obtained by sucrose gradient ultracentrifugation. This method gave one initiation per 40,000 nucleotide pairs.

The figures are acceptably close and correspond to 150.000 polymerase B initiation sites per diploid calf nucleus. The upper limit, given by population genetics, for the number of independent genes per haploid genome is 50,000, that is, 100,000 per diploid nucleus. The number of sites is intriguingly close to the number of genes but, wisely, nobody is jumping to conclusions at this stage. In a long nucleotide sequence a given sequence of seven nucleotide pairs has, to a first approximation, a probability 1 in 65,000 of occurring by chance. Cedar found one initiation site per 50,000 nucleotide pairs with calf thymus B and *E. coli* DNA so the polymerase may recognise a nucleotide sequence about seven nucleotides long that occurs by chance in *E. coli*.

The number of initiation sites is further restricted in chromatin. On average, one initiation was found for every 400.000 nucleotide pairs in calf thymus chromatin in solution, which implies 15,000 initiation sites per diploid nucleus in calf thymus. This is comparable to the estimated number of active genes although it may be a little higher. The

number of initiation sites could be higher than the number of genes expressed if the cell transcribes sequences that do not contain a gene or if many genes have multiple initiation sites. It is also possible that some or all of the initiations observed *in vitro* do not occur *in vivo*. In order to investigate the relationship between the *in vivo* and *in vitro* RNA transcripts their nucleotide sequences must be studied. It is becoming possible to do this directly and some 5'-terminal sequences of nuclear RNAs are appearing (see *Nature*, **255**, 9; 1975). Alternatively molecular hybridisation techniques can be used, especially when a particular gene can be isolated or a cDNA copy of a pure messenger RNA obtained, which can then be used as a highly specific probe for the transcription of a particular gene.

Breeding for protein yield and quality

from Donald Boulter

THE relative importance of protein, as opposed to protein/calorie deficiency, on a world scale, continues to be debated (P. Payne, *New Scient.*, 7 November, 1974), although most of the arguments are of the paper and pencil calculation type. Whatever the final outcome of this debate, it should not obscure the fact that most field workers agree that there is a need to increase the productivity and to stabilise the yield of high protein crops, particularly of legumes since these can fix atmospheric nitrogen.

In diets in many developing countries, legumes play a significant part in supplying protein, as well as in improving soil fertility, and the first priority is to stabilise yield by breeding more resistant lines and then to increase productivity by improved management and restructuring of the plant type. A likely result of such improved legume varieties is an increase in protein yield. Where small amounts of food are required, for example by young children, the total amount of protein consumed is small and any nutritional deficiency of that protein prevents complete utilisation of it. In this situation an improvement in protein quality is essential; this applies both to cereal- and legume-based diets. With adults the available information on diets is insufficient to show the extent of the need for improved protein quality. Also, alternatives such as influencing dietary patterns so that protein from one source may nutritionally supplement that from another, will also have a role. However, in diets in which the main staple is cassava and possibly in those using other roots or

tubers, the quality of the protein consumed may be inadequate for its complete utilisation; here sulpho-amino acids are likely to be first-limiting.

Many of the problems involved have been discussed recently at the Third Research Coordination Meeting of the FAO/IAEA/GSF Seed Protein Improvement Programme, held in Hahnenklee, FDR, 5–9 May 1975

The plant breeders at the meeting were firm in their belief that, to be acceptable to farmers, varieties improved with respect to protein quantity and quality must have high and dependable yields. The one exception to this generalisation is where such varieties might be grown as premium crops where quality brings additional income, a relatively uncommon situation particularly in developing countries. The long-assumed negative relationship between protein yield and grain yield is now known not to be generally valid and in wheat and rice, for example, improvement in both characters has been achieved simultaneously. As long as the demand in a cereal crop for protein content is not excessive, a few percentage points increase, significant advances can be made without sacrificing grain yield. In soyabean, restructuring has achieved very high protein content and high yields.

The same cannot be said, at this time, for protein quality. The experience with high lysine maize, barley and sorghum all point to somewhat reduced yields of grain when genes for increase in lysine are included in a genotype. But it was generally agreed that attempts to incorporate high lysine genes into other genetic backgrounds were only beginning.

J. Axtell (Purdue University) described investigations on natural and induced genes for high lysine in grain sorghum. In this work, a population of seeds was treated with the mutagen diethyl sulphate and selections were made in later generations for the opaque endosperm character by passing seeds over a light box Only certain opaque endosperm genotypes also carried the high lysine character. The desirable endosperm types have been grown for additional generations, but some showed highly deleterious characters as well. Nevertheless, a high lysine endosperm type with good growth characteristics has been recovered (P–721).

R. A. Olson (University of Nebraska) had documented considerable variability in soil conditions in fields used for growing breeding materials for protein improvement, and showed that, probably as a result, the protein content of the plants varied. In the same vein, W. Gottschalk (University of Bonn) presented results from field pea

genotypes in which ranking in both protein content and grain yield were shown to fluctuate widely from year to year. This result is in contrast to those obtained with wheat and barley trials carried on elsewhere, wherein the rankings remained relatively constant between locations and years. Walther (Grünbach, FDR) presented results with barley showing that in an experiment with adequate replication in seasons and locations, it is possible to elucidate plant responses with respect to yield and protein content with apparent reliability. All of these results taken together re-emphasised the difficulties in protein breeding due to gene/ environment interactions, and the necessity for interpreting early results cautiously.

L. Munck (Carlsberg Laboratories, Copenhagen) considered the prospects for the use of high-lysine grains in the animal feeding industry. First, the industry must appreciate the nutritive advantage of high-lysine grains when considering the inventory of the available feeding materials. Second, evaluating procedures need to be available; for example, Munck suggested dyebinding, used in parallel with Kjeldahl nitrogen determination, as a possible means of recognising high-lysine feedstuffs. Only then would feedback pressure on the plant breeders lead to the general inclusion of the high-lysine character in their breeding objectives.

It is well known that legumes are nutritionally deficient in sulpho-amino acids, and D. Boulter (University of Durham) pointed out that it is necessary to consider both sulpho-amino acids, methionine and cysteine, in work on breeding for improved protein nutritive value in legumes. It seems possible to use total seed sulphur as a coarse ranking indicator of the sulpho-amino acids for screening of some legumes In those legumes which contain relatively large amounts of S-methyl-cysteine, sulphur must be determined after removal of this amino acid by extraction with 70% alcohol. Both Boulter and R. M. Gillespie (CSIRO, Glen Osmond, South Australia) suggested that there are reasonable prospects for being able to breed for improved nutritional value by altering the proportions of the major seed proteins which contain different amounts of sulpho-amino acids. In Boulter's view however, present indications are that the range of variation in the protein sulpho-amino acid content of legumes in breeding programmes is small enough to warrant considerable effort in the assembling of world collections.

A new dimension to this problem was furnished by the work reported by Gillespie (see Blagrove and Gillespie, *Aust. J. Plant Physiol.*, **2**, 13–27; 1975;

Gillespie and Blagrove, *Aust. J. Plant Physiol.*, **2**, 29–39; 1975). They have found that in lupins the relative proportions of the major seed proteins can be changed up to a point by supplying sulphur at different levels; in high-sulphur treatments the proportion of a high-sulphur protein was increased. Thus, there is a strong gene–environmental interaction, although whether the effect is directly on gene expression at the transcription or translation levels, or whether it operates by a changed physiology, is not clear. It will be of great interest to see how general these results are for other legumes.

T. Behre (Debre Zeit, Ethiopia) reported a breakthrough on breeding *Eragrostis tef*, which represents a significant source of protein in Ethiopia. Up to now, all attempts at controlling the pollination of this crop have been unsuccessful. But as a result of studying the basic reproductive process of the plant, it has been possible to perform hand pollinations, so that normal procedures of plant breeding may be applied and it should now be possible to make improvements in yield through breeding.

In the realm of improved techniques for screening and evaluating the nutritional quality of advanced lines, there was an encouraging report concerning the use of a fluorescence technique for the specific determination of lysine in ground samples of grain. Less advanced is some work on a similar technique for tryptophan determination. Both of these developments were reported by A. K. Kaul (Institut fur Strahlenbotanik, Hannover).

A number of contractors from developing countries reported progress on the development of improved protein genotypes in several crops, including bread and durum wheat, rice, barley and several legumes. Because of the early stage of the work, no attempt is made to detail the results here, but a general feeling of optimism prevailed For example, H K. Jain (New Delhi) was convinced that tropical legumes as a group were excellent materials in which great improvements could be achieved.

A homogeneous Universe?

from Malcolm MacCallum

THE simplest cosmological models assume the Universe to be spatially homogeneous and isotropic Isotropy, the equivalence of all directions from us, is on a fairly firm experimental basis provided by observations of the cosmic microwave background, the X-ray background and so on, although there are contradictory results (Brown, *Mon.*

Not. R. astr. Soc., **138**, 527; 1968; Wilson, *Mon. Not. R. astr. Soc.* **155**, 275, 1972) demanding further investigation. However, isotropy does not directly imply homogeneity, the equivalence of all points in space, for we might simply be at 'the centre of the Universe'. There is a strong anti-geocentric prejudice which favours homogeneity, but a lack of observational evidence.

The prejudice itself is recent. Only in 1918 did Shapley find the Sun was not at the centre of our Galaxy, three and a half centuries after Copernicus's discoveries. It was 1924 when Hubble proved some 'nebulae' were galaxies and 1952 when Baade's revision of the cosmic distance scale showed other galaxies could be as large as our own. The 'Copernican principle' and its strong form, the assumption of homogeneity, have subsequently been almost articles of faith, especially as they have the practical advantage of simplicity.

This attitude is reinforced by the difficulties of observationally checking homogeneity, arising because it involves a knowledge of conditions at all points, however distant. All one can hope to say is that any inhomogeneity has a scale greater than our range of observation. If the latter included our whole past we would know all we really require. But the finite velocity of light means we must compare distant objects as they were in the past and not as they are now, so we need to know about the evolution of both individual astrophysical objects and the Universe as a whole to make the comparison

In spite of these difficulties, our view about homogeneity is naturally influenced by knowledge of the cosmic structure in our vicinity. The most obvious feature to test is the distribution of galaxies. It is now well known that galaxies are clustered and so not homogeneously distributed. de Vaucouleurs (for example in *Science*, **167**, 1203; 1970) has expounded a theory of a hierarchy in which clusters are grouped in superclusters and so on Peebles and collaborators (*Astrophys. J.*, **196**, 1; 1975) found no evidence of a hierarchy in their extensive statistical investigations of catalogues of galaxies. They concluded that there is a continuous spectrum of clusters on scales $10/h$ kpc to $5/h$ Mpc, where h represents the time cosmic distance scale in suitable units and 1 pc is roughly 3×10^{13} km. Current estimates of h are roughly in the range $\frac{1}{2}$ to 1. This distribution could be the effect of gravitational attraction within initial accidental density enhancements, the clusters themselves being homogeneously distributed.

Turner and Gott (*Astrophys. J.*, **197**, L89; 1975) have just announced a new development. They were studying the problem of the non-luminous 'missing mass' that may be required to gravi-

tationally bind clusters of galaxies, by examining the dynamics of small groups of galaxies. To find such groups they took all Northern Hemisphere galaxies brighter than fourteen magnitude (which corresponds to a distance of order roughly 100 Mpc) at more than forty degrees from the galactic plane, and separated these into two classes according to whether their nearest neighbour was at an angular separation greater or less than 45 minutes of arc They noted that the more isolated class appeared to be homogeneously distributed in the sky, and thus tried applying Peebles's statistical methods to each class separately. They found the 'isolated' class, about 40% of the total, were indeed homogeneous, once effects of galactic obscuration and statistical noise had been allowed for. The other class however showed strong clustering on scales up to eight degrees.

This result, which invites further examination, will, if confirmed, leave us awkwardly poised. Each of the two classes separately is reasonably explicable, but Turner and Gott show from velocity and brightness data that they must be intermingled, and how one class became clumped while the other did not is a mystery. Once again nature proves to be more complex than was thought.

Of bedsteads and neutrons

from James Binney and Philip Candelas

INTEREST in the interaction of quantum theory and gravitation has been growing recently. Following Hawking's sensational prediction (*Nature*, **248**, 30; 1974) that black holes may emit photons and other elementary particles, several recent publications have discussed the importance of quantum effects in strong gravitational fields (see review by DeWitt, *Physics Reports*, in the press; and *Quantum Gravity: An Oxford Symposium*, edit. by Isham, Penrose, and Sciama; Oxford University, 1975).

Just to make sure we have the basics right Colella, Overhauser and Werner (*Phys. Rev. Lett.*, **34**, 1472; 1975) have been checking up experimentally that the de Broglie waves associated with neutrons really are refracted by a gravitational field in the same way that proton wavepackets are refracted by an electric field. Colella and co-workers have cut from a single crystal of silicon a device which operates much as a Young's double slit experiment. Bragg diffraction in one part of the crystal splits a neutron beam into two, each being subsequently diffracted back towards the other by another part of the crystal. Colella *et al.* then monitor

the intensity of the signal produced by the interference of these two beams in a third part of the crystal. They find that the relative phase of the two interfering beams changes as elementary quantum mechanics predicts it should when the apparatus is rotated so as to alter the relative inclination of the two beams to the horizontal.

Of course one is not very surprised that the result of a low-energy experiment of this type is accurately predicted by conventional quantum theory. It is unfortunate that weak gravitational fields should be the only ones accessible to experiment since recent remarkable results due to Hawking and Beckenstein indicate profound interrelations between quantum theory, gravitation and thermodynamics.

Hawking discovered that, in the case of a realistic black hole formed by stellar collapse, effects to do with the quantum fluctuations of the vacuum cause real particles to be produced and emitted to infinity as a constant flux. What is really astonishing about Hawking's result is its form. The outcome of his highly sophisticated analysis is that black holes should radiate photons and other particles precisely as if they were black bodies of definite temperature. The temperature is inversely proportional to the mass of the hole.

Surprisingly, this result is essentially that suggested earlier by Beckenstein (*Phys Rev.*, **D7**, 2333; 1973) from an entirely different, very classical argument : Take a large, brassy Victorian bedstead and consider it carefully for a moment. You observe four legs, many knobs and springs. Indeed if you are a connoisseur of such things you might well guess that it was manufactured in Bristol in 1864. Toss this same bedstead into a black hole and all this information is suddenly lost to you. The only differences that you observe in the hole are small changes in its mass and angular momentum. But of course a loss of information implies an increase in entropy, an effect which one can quantify. In this way Beckenstein was able to put a value on the entropy of a black hole, which turned out to be proportional to its surface area. From this followed in a formal way a value for its thermodynamic temperature. What Hawking showed us was that this formal temperature is perfectly real.

Thes two results fit beautifully with work by Bardeen, Carter and Hawking (see for example Carter's contribution to *Black Holes*, edit. by DeWitt and DeWitt; Gordon and Breach, 1973) who showed that changes in the configuration of a black hole are constrained by a series of laws analogous to those of thermodynamics. This similarity was at first thought entirely

formal with the inverse of the black hole mass having the role of temperature and the area of the black hole behaving like entropy. Now in the light of the work by Hawking and Beckenstein we see that there is a complete identification of black hole parameters and thermodynamic variables.

It is very encouraging that a field as young as is the study of quantised particles in gravitational fields should already have produced a much needed piece of the jig-saw of physics. A host of cosmological problems seem to require for their solution a better understanding of these quantum processes. Perhaps with the solution of these other problems we will again obtain important and unexpected insights into the nature of things.

Spots before the eyes

from E. G. Richards

A RECENTLY published two-dimensional electropherogram shows the resolution of more than 1,100 proteins from *E. coli*. This spectacular result is to be found in a paper by O'Farrell (*J. biol. Chem.*, **250**, 4007; 1975):

T w o - dimensional electrophoresis involves the separation of a mixture along the first dimension according to some molecular property of the components; this is followed by movement of the components in a perpendicular direction resulting in separation according to another property. Most attempts to apply such methods to mixtures of proteins have suffered from correlations between the two chosen properties resulting in a tendency of the components to cluster round a diagonal in the final pattern.

O'Farrell has played the simple trick of separating according to isoelectric point by isoelectric focusing in the first dimension followed by a separation according to molecular weight by SDS-polyacrylamide electrophoresis in the second The isoelectric point and molecular weight show virtually no correlation.

To summarise his method, the separation in the first dimension is conducted in a 2½% cylindrical polyacrylamide gel containing 9 M urea and ampholines to produce a *p*H gradient between *p*H 5 and 7. For the second dimension a 0.8 mm thick flat bed gel of polyacrylamide with an exponential concentration gradient and containing SDS is used. The sample to be applied is first treated with nucleases to remove RNA and DNA which otherwise produce streaking effects and then the proteins are solubilised and denatured in 9 M urea before application to the first dimension. After the first separation

the isoelectric gel is advantageously equilibrated by shaking in SDS solution before incorporation into the flat bed gel. Although this equilibration leads to some loss of proteins and some impairment of the resolution, it further reduces streaking.

The authors claim that about 70 bands can be resolved in the first isoelectric separation, and up to 100 in the second SDS dimension. Thus a maximum of 7,000 proteins could in principle be resolved though this figure may be reduced somewhat in practice for a variety of technical reasons. Nevertheless the authors have counted more than 1,100 spots obtained from the application of whole *E. coli* extracts. A rough calculation which assumes a chromosome of 4 million base pairs and a thousand of these to each protein gives an upper limit of 4,000 different proteins in *E. coli*.

Two detection systems were utilised : staining with Coomassie blue and autoradiography with the use of ^{14}C labelled proteins. The first method can detect 0.01 *µ*g of protein in a spot; the second, in a twenty day exposure, can detect 1 c.p.m. which could correspond to a protein which existed in but one copy per cell at realistic, albeit high, specific activities. However these detection limits are by no means the whole story since the picture is complicated when the total load of protein is raised to enable minor components to be detected. In the first place the total protein load must be kept low to avoid streaking effects and other distortions of the spot shape; in the second the size of a spot was found to increase when the amount of protein in it increased. This means that minor components located close to abundant proteins would be hidden and remain undetected.

The authors claim that replicate runs are highly reproducible provided the conditions are carefully standardised and ampholines from the same batch are used. The comparison of two electropherograms is facilitated by the characteristic patterns of spots produced

If the author's recipes are not carefully adhered to, certain artefacts may be introduced such as streaking and multiple spots due to charge heterogeneity and solubility problems.

It would thus sem that a new tool of considerable power has arrived and it will be interesting to see what use is made of it O'Farrell himself says that the method as it stands does not work for basic proteins such as ribosomal proteins and histones but one may guess that there are no insuperable problems in adapting it for such mixtures. Maybe the characteristic patterns of spots will also commend themselves to taxonomists.

review article

Computer-aided thought in biomedical research

W. J. Perkins & B. J. Hammond*

With the technology at present available, computers are potentially more than simply mindless calculating machines. They can now be programmed to make intelligent use of the ideas researchers have about the problems they are trying to solve.

The human mind is seldom satisfied, and is certainly never exercising its highest functions when it is doing the work of a calculating machine. What the man of science, whether he is a mathematician or physical enquirer, aims at is to acquire and develop clear ideas of the things he deals with. For this purpose he is willing to enter on long calculations and to be for a season a calculating machine, if he can only at last make his ideas clearer.

J. C. Maxwell (1870)[1].

THE relationship between the man of science and his calculating machine has undergone, particularly in recent years, a rapid evolution but it is the machine and not the man that has changed. For in spite of the almost overwhelming power of a modern computer, the scientist still simply seeks to 'develop clear ideas of the things he deals with'. The calculating power that evaded Maxwell's grasp has since become a common-place means of evaluating data from scientific experiments but it is equally well established that the computer is, at least potentially, more than an outsize calculating machine. Substance is being added to this view, albeit slowly, by research in those areas of computer science gathered somewhat uneasily under the umbrella of artificial intelligence[2], but for the scientific user the more exciting prospects must at present remain as unredeemed promises. It is nevertheless possible to marshal a sufficient range of techniques, both in hardware and software, to provide the researcher with an effective tool for processing ideas as effectively as he may process numerical data.

An illustration of the difference between these two activities is seen in the application of computers to the problem of virus structure. The electron microscope provides pictorial views of individual viruses seen from various angles but, because of the preparative procedures and the fact that the microscope is operating at its limit of resolution, the images obtained are difficult to interpret in terms of three-dimensional structure. The electron micrograph may, however, be scanned automatically and reduced to an array of density data in a computer, thus allowing various lengthy mathematical transforms to be applied in attempts to improve the resolution of the record, or to make symmetry relationships more explicit. It is also possible to reconstruct the three-dimensional shape of a virus from a series of electron micrographs of a given specimen taken at various tilt angles, though at present, radiation damage of the specimen limits the number of exposures that can be made and so restricts the technique to highly symmetrical structures[3]. This data processing approach is designed to help in building a mental picture of virus structure but it makes little use of the tentative ideas that the researcher may be carrying in his head at any time.

*Address: The National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

Ideas about the possible shapes of a virus find a more direct means of expression in the use of physical models, which act both as a focus and an embodiment of the researcher's thinking and can be changed almost at will as shortcomings of particular structures are recognised. A more sophisticated and more flexible extension of the physical model can be obtained if the model is computer-based but, particularly in the early stages of model development, there is a need for more rapid assessment of ideas than that provided by off-line computer facilities. Close interaction between modeller and model is needed if the computer is to aid and not frustrate creative thinking of the user.

Hardware and software

From the technical point of view then, it is necessary to exploit to the full those computer facilities that speed communication, in either direction, between man and machine so that a computer intended as a thinking-aid is characterised more by its range of operator input–output devices than by an impressive size. Such input devices include, in addition to the standard keyboard, simple switches and potentiometers for indicating binary conditions and analogue levels to the machine, graphic tablets for communicating line contours to the computer, and the light-pens and joy-sticks used in conjunction with output displays to signal positional information. Interactive output facilities, in addition to the standard teleprinter or its electronic equivalent, encompass various oscilloscope devices for displaying line drawings in a storage or non-storage mode and television-type displays for presenting continuous tone or coloured picture information to the user.

The provision of suitable hardware is necessary but not

Table 1 Keyboard commands for rotating computer model of adenovirus hexon

a Building instructions

Command	Description
BR/X./Y./Z./	Bring a cell into position
JN/-N/φ./ψ./	Join on to cell N at given angles
SH/--N/-N1-N2/	Show number of cell N. Type coordinates N1 to N2
DE/--M/--N	Delete cells M to N
MST/M/-N	Make a structure numbered M
BRS/-N/X./Y./Z./θ./ψ./	Bring a structure into position given
BN/--N/	Add background of N dots per inch²
RE/	Read in a structure
OU/	Output a structure

b Rotation instructions

Command	Description
AX/N/φ./θ./	Set angles of axes for quadrant N
RTX/θ./	Rotate structure about X by angle θ
RTY/φ./	Rotate structure about Y by angle φ
RTZ/ψ./	Rotate structure about Z by angle ψ

Fig. 1 *a*, Basic model of adenovirus hexon in the orthogonal planes; *b*, various orientations of the adenovirus hexon model; *c*, electron micrograph of adenovirus hexons showing diverse orientations.

written in autonomous blocks. Modular programming provides a suitable software structure that implements the various model manipulations as a set of self-contained blocks to which changes, additions and deletions may readily be made as modelling requirements change with a model's evolution.

Interactive graphics

One basic way in which hardware and software may be coordinated to provide an aid to thought lies in the use of interactive graphics, which can best be illustrated by returning to the problem of virus structure. A modular program has been developed that allows the interactive building of tentative virus structures using spheres as basic building units. The keyboard commands for the control of model building are shown in Table 1 and the three-dimensional nature of the structure is presented to the user as orthogonal projections on a storage display screen. Starting with a blank screen the user can type bring (BR) commands to establish single spherical units at specified coordinates and further units can be attached to existing units by use of a join (JN) command. Each unit is allocated an identification number as it is entered on the screen and the identity of a specified unit can be retrieved at any time using a show (SH) command. Units can also be removed from the structure by means of a delete (DE) command. Another useful building feature is the ability to mark and store a structure using an MST command which subsequently allows the marked structure to be used again, either in its own right or as the subunit of a grander design.

These few commands, with the immediate presentation of their effects on the model, allow effective interaction between user and computer in building plausible models of virus structure; this is illustrated by Fig. 1*a* which shows a model of an adenovirus hexon, built up in this way and displayed in the orthogonal planes. The human contribution to the man–machine interaction is not only his speculative ability but his ability to compare the geometric properties of a model with the fuzzy images provided by the electron microscope. This comparison can be assisted by randomly filling the spherical building units with a suitably dense distribution of dots to indicate depth. In addition, a random distribution of dots at any selected level can be added as a background to the model. By the use of the further keyboard commands given in Table 1, the model can be rotated about all axes to present planar orientations that can be compared directly with the two-dimensional projections observed in electron micrographs of the virus specimens. The diverse patterns observed during rotation give ideas as to how other patterns might be obtained then the model can be refined to obtain a closer match. Various orientations of the adenovirus hexon model may be seen in Fig. 1*b* and related to the diverse projections observed in the electron micrograph of Fig. 1*c*. The distribution of categorised patterns in the model may also be compared with distributions in electron micrographs for different preparative procedures to assess their effect on the patterns obtained.

Three-dimensional displays

Two-dimensional projections of computer-implemented structures are progressively less useful as three-dimensional complexity increases, but there is no difficulty in transforming the data in the computer to produce a stereo display[4]. An example of this approach features molecular models of proteins where the user, viewing a large screen oscilloscope through a suitable mirror system, sees the appropriate network of straight-line bonds as a three-dimensional structure in space. The space relationships can be further clarified by rotating about orthogonal axes using manual potentiometers interfaced to the computer through A–D converters. This presentation is at first dramatic but is no more than a computer-based version of conventional ball and stick models, that is, until interactive facilities are added to the basic facility.

sufficient to establish close interaction between user and computer; effective interaction also lies with effective programming. A difficulty arises in the fact that in the present context the models are by definition tentative, and the nature of any changes that may subsequently be required cannot be clearly foreseen, yet an interactive program should at the outset provide the user with a sufficient range of alternative model manipulations at least to launch the model on its uncharted course of development. Subsequent program changes will almost inevitably be required, either to modify the nature of the model or to provide further manipulation facilities, and the ease with which these may be implemented depends to a large extent on the degree to which the program has been

Consider for example the molecular conformation of complex molecules where the sequences of atomic components are largely known but where the structure still retains sufficiently numerous degrees of freedom to generate an immense number of possible second order configurations. The configurations preferred by nature are those of minimum energy but the determination of this condition for a complex molecule by an unguided search is usually rendered impracticable by the sheer number of candidates to be considered and by the numerous local minima observed[5]. In practice the researcher seeking natural conformations bounds the search according to largely empirical rules, but if a closely interactive approach is adopted, available clues from other sources may be incorporated together with experience, ideas and sometimes intuition. Three-dimensional displays of the molecular structure provide an effective focus for such interaction and control of the conformation of the structure is readily provided by manual potentiometers that specify particular bonding angles and can therefore be used to rotate one part of the structure relative to the remainder.

At any point in the interaction the user may call for energy calculations to be made corresponding with the incremented rotations of a specified bond about two orthogonal axes. This information can be presented in a variety of ways but each uses the mapping of energy values on to a plane defined by axes of the incremented variables. The more sophisticated displays present the user either with constant energy contours or with two-dimensional views of the energy surface constructed above the reference plane. In either case a rapid assessment of the current situation can be made and serves to direct the next step in pursuit of a minimum energy configuration[6].

Conversational mode

The interactive manipulation of complex molecules places its heaviest technical demands upon communication from machine to man but in other situations, communication in the reverse direction is more important. The man-to-machine link is made through a coded instruction chosen from a prearranged list. If the idea of an instruction is, however, interpreted too rigidly, that is, if it is taken to imply an imperative requiring no response other than blind obedience, then the onus for precise expression of complex instruction formats falls entirely on the user and any operator errors will generally cause the computer program to abort. The consequent loss of rapport between man and machine can, however, be restored by upgrading the role of the computer as an instructed device, so that it apparently takes the initiative whenever a decision is required. At such times the computer explicitly invites a decision, checks the validity of the user's reply and then, by prompting, guides the user along the chosen path of action. In this way a conversational mode of control evolves in which the real prerogative of choice remains with the man, while the tedious responsibility for its appropriate expression is largely taken over by the machine.

An illustration of the conversational mode arises with an interactive model that has been formulated to explore ideas about the establishment of neural connections between the retina of the eye and the tectum during an animal's development. It is known that the retinal cells are eventually mapped, by their connections, in a spatially ordered manner on to the tectum and the model therefore allows the implementation of various schemes by which the ordering process may be controlled[7]. Critical assessment of particular schemes is provided by model manipulations that mimic experiments that have been carried out to perturb the developing retinotectal system by various surgical interventions. Whenever the computer is ready for a fresh instruction it types out the query 'OPTION =' and the user may then reply with a simple mnemonic option code selected from a list of some 40 alternatives. One set of codes allows the current state of the model to be examined by calling for the display of tectal mappings corresponding to various points or straight lines drawn on the retina. Other codes control the sizes and rotations of the retina, tectum and tectal grafts
Fig. 2 One of several optional display facilities traces the rows and columns of the current retinal array as mapped on to the tectal array at any time. The result of executing an ordered mapping is shown in *a*, while *b*, *c* and *d* show the display as it appears after each retinal cell termination has been allowed a random walk on the tectum of 1, 5 and 100 steps respectively.

while the initial mapping of retinal cells on to the tectum, in either random or ordered fashion, is controlled by further codes. All option codes are checked on receipt by the computer and in the event of operator errors the user is asked to restate his chosen option; in the absence of code anomalies the computer asks for any further information, usually numerical, necessary to fulfil the particular option. This information is checked before implementation to ensure that impossible conditions, such as mapping the current retina on to too small a tectum, are not implied in the user's choice.

Further, more basic options implement changes in tectal termination positions, for example by allowing each termination the freedom of a random walk. When the random walk option is applied to an initially ordered mapping of retinal cells on to the tectum, the display of a rectangular retinal lattice mapped on to the tectum is subject to ever-increasing randomisation as shown in Fig. 2. This effect accompanies the assumption that, during development, retinal cell terminations possess an innate mobility on the tectal surface and in order to achieve the spatially ordered mapping observed in mature animals, the tectal ordering mechanisms must oppose, indeed reverse, this randomising tendency.

One scheme that has been found to order a random tectal mapping involves comparison of the retinal cell locations corresponding with neighbouring tectal terminations. Each termination is considered in turn and interchanged with a randomly selected neighbour if, and only if, its tectal position with respect to that neighbour contradicts the relative positioning of the corresponding retinal cells. In experimenting with this scheme applied to more complex model conditions some unexpected modes of behaviour have been observed. For example, when half of a tectum is rotated through 180°, so reversing its sense of direction, it was expected that a random mapping of retinal cells on to the compound tectum would
Fig. 3 The rectangles represent the maximum and minimum interpretations of field data recording the daily numbers of persons susceptible to infection (S), the number infected and assumed to be infectious (I) and the number recovered from a common cold infection as functions of time (R). The dots show the corresponding performance of a dynamic model evolved using interactive hybrid simulation.

of simultaneous differential equations. In these cases the addition of an analogue integration capability to an interactive facility can greatly enhance the speed and hence the effectiveness of communication.

The contribution that can be made by analogue integration is illustrated in an example from the field of epidemiology[3]. In spite of a great deal of analytical work on mathematical models of the epidemic process, the validation of even basic model assumptions has been hampered by lack of suitable field data. For such validation, accurate dynamic data are required concerning a small, but not too small, isolated, homogeneous and gregarious community into which a single infection is introduced. This requirement was apparently met when seven sets of data became available concerning common cold outbreaks on the island of Tristan da Cunha. The form of these data is shown in the upper part of Fig. 3. A flexible scheme of differential equations was therefore formulated to embrace some of the alternative ideas used in existing models of the epidemic process and the equations solved by interfacing standard analogue computer modules to perform the necessary integrations. A fast solution time (80 ms) was obtained and warranted the presentation of the solutions on a display screen concurrently with selected sets of field data. This enabled the immediate appreciation of changes in model behaviour corresponding with changes in mechanisms and values incorporated in the model structure.

A model was thus evolved that agreed well'with five sets of field data but the remaining two sets remained enigmatic since experiments with the model showed that the most acceptable explanation lay in the unlikely event of a double infection involving different viruses. Since the most likely source of such viruses seemed to be the occasional visiting ship, the records of ship arrivals were examined and the occurrence of the two anomalous epidemics were found to follow the almost simultaneous presence of two visiting ships. The agreement between model and data in one of the double infection situations is shown in Fig. 3.

eventually be ordered as if half an ordered tectum had been rotated. This idea was promptly revised when the model was observed to behave as two quasi-autonomous tecta that independently ordered their quota of randomly allocated terminations.

Dynamic systems

The eventual explanation of retinotectal mapping must have some dynamic content since changes occur in both temporal and spatial domains. In many other situations the changes that take place with time, eclipse any detailed interest in changes that occur with spatial dimensions and the geometric content of the corresponding models is reduced to the gross representation of structural features as they affect dynamic performance. This transition is highlighted in the use of compartmentation schemes, perhaps most familiar as descriptions of metabolic or drug distribution systems.

The derivation and implementation of dynamic models using computers is a subject of sufficient substance to be recognised as a separate discipline, that of computer simulation. Little of the simulation work on biological systems, however, has been carried out in sufficiently close interaction with the machine to exploit the computer simulation route to computer-aided thought. One reason for this lies in the use of high level computer simulation languages which considerably ease the burden of programming, but in execution the resultant programs are often too slow and inflexible to support on-line thinking. At least at present, custom-built applications programs remain advisable and may conveniently follow the same guidelines, and provide the same interactive facilities, as those required for the effective manipulation of purely geometric models. In terms of hardware, however, the requirements for geometric and dynamic models are not identical since many of the latter, typified by compartmental models, find their natural formulation in terms

Present position

The essence of computer-aided thought is the effective interfacing of the conceptual prowess of man with the manipulative capability of the computer. At present, and possibly for some time to come, the finesse with which this can be accomplished is limited by available technology, but yet provides an effective means for accelerating the development of ideas. The real impediments to this use of computers in biomedical research are thus not basically technological but would seem to be more of human origin. First, the idea of computer-aided thought has not in general been brought to the attention of the biomedical researcher, at least not in a comprehensible way, so that there is little motivation to explore its application to his own work. Second, since specific ideas are to be tested, they require specific programs of some complexity in order to obtain the closeness of interaction needed for this type of application and the average biomedical researcher is rarely willing to devote the time and effort needed to acquire the necessary expertise for this purpose. Last, even where suitable facilities exist, the computer specialist is often distracted by the demands of his own subject from understanding a biomedical problem in sufficient depth to provide the researcher with an appropriate and effective means of interaction with the computer.

These problems are by no means unique, indeed they are quite familiar in other fields including that of bioengineering where it has been recognised that an engineer needs more than a superficial knowledge of biomedical subjects if he is to be maximally effective. Computer scientists specialising in biomedical applications may need to follow a similar pattern if the computer is to be fully exploited as a research tool.

Amplification of a specific region of the polyoma virus genome

Beverly E. Griffin & Mike Fried

Imperial Cancer Research Fund, PO Box 123, Lincoln's Inn Fields, London WC2A 3PX, UK

Defective DNAs, isolated from mouse cells after infection with a clonally purified stock of defective polyoma virus, have been found to consist of nucleotide sequences from about 17% of the wild-type polyoma genome, tandemly repeated two to six times. These sequences come from the region of the viral DNA which contains the origin of DNA replication and the 5' ends of early and late stable mRNAs.

THE genome of polyoma virus is a supercoiled DNA molecule composed of about 5,200 pairs of nucleotides, and has a coding capacity for approximately 200,000 daltons of

protein. Polyoma virus can undergo at least two different types of interactions with susceptible cells. One interaction results in the death of the cell concomitant with an increase in the number of virus particles (productive or lytic infection). The other results in cells acquiring a set of characteristics which resemble those of tumour cells (nonproductive or transforming infection). When cells that are capable of being lytically infected are treated with high multiplicities of polyoma virus (high virus to cell ratios), virus particles containing non-infectious supercoiled DNA molcules, heterogeneous in size, are produced. With continued high multiplicity passage, particles containing this non-infectious DNA, termed 'defective' DNA, will come to predominate the virus stock[1-3].
Fig. 1 Autoradiograms showing electrophoretic separation of the different ^{32}P-labelled DNA species obtained following infection of 3T6 mouse cells with D-50 clonal isolates. Virus stock grown from the clonal isolate containing D-50 molecules[3,5] and wild-type helper virus, was used to infect 3T6 cells in low phosphate media in the presence of ^{32}P-phosphate[6]. Viral DNA was selectively extracted from infected cells[15] and supercoiled DNA molecules purified by CsCl equilibrium centrifugation in the presence of EtBr (ref. 16). The band containing supercoiled DNA was isolated and the EtBr removed by extraction with CsCl-saturated 2-propanol[16]. DNA was recovered by alcohol precipitation after diluting the aqueous solution threefold with Tris-EDTA (10 mM-1 mM). This DNA was further separated into a number of species by electrophoresis on 1% agarose cylindrical gels (SeaKem agrose, 0.8 × 15 cm) with E buffer[14]. The various gel bands (1-5) were located by autoradiography, excised, and DNA eluted by electrophoresis into dialysis membranes[17]. The sizes of the DNAs from bands were determined by their sedimentation properties in 5-20% sucrose gradients[3]. By these procedures, the calculated sizes[21] of the various DNA species were estimated to be about 34, 51, 68, 85 and 102% wild type genome length. Bands : 1, 102% defective supercoiled molecule and wild type helper supercoiled DNA; 2, 85% supercoiled defective molecules; 3, 68% supercoiled defective molecules; 4, 51% supercoiled defective molecules; 5, 34% supercoiled defective molecules. (The bands migrating more slowly than Band 1 contain linear and nicked circular forms of the different defective DNAs and various species of mitrochondrial DNA.) Gels: *c*, Supercoiled DNA from 3T6 cells infected with the original clonal isolate[3] of D-50 virus. *a* and *b*, Supercoiled DNA from 3T6 cells infected with a virus derived from purified D-50 molecules and added wild type helper viral DNA. (The D-50 molecules were purified and isolated as supercoiled species first from sucrose gradients[3], followed by CsCl-EtBr density gradient centrifugation[16], before being combined with the wild-type helper DNA to produce the virus stock.) *a* and *b* differ only in the length of time the gel was exposed to the X-ray film.

Fig. 2 Autoradiogram showing the position of restriction enzyme fragments from ^{32}P-labelled polyoma wild type (A-3 strain) DNA and D-50 DNA. Separation was accomplished by electrophoresis on a 4–7% acrylamide slab gel (20 × 40 cm) in Trisborate buffer (pH 8.3). The division between the two gel concentrations is indicated. 1, Fragments 1–8 obtained after cleavage of A-3 DNA with *Hpa*II; fragment sizes are given in parentheses (at left). The DNAs obtained from A-2 and A-3 polyoma virus stocks (both Pasadena large plaque strains) differ in the size of fragment *Hpa*II-5. This fragment is 7.7% genome length in A-2 (ref. 6) and 7.4% in A-3 DNA[6], the change occurring near the *Hpa*II 3–5 junction (B.E.G., unpublished). D-50 and related defective DNAs have the smaller *Hpa*II-5 fragment characteristic of the A-3 strain. 2, Two main fragments obtained by *Hpa*II cleavage of D-50 DNA. The single product (about 17% genome length) from a limited digest is seem to migrate slightly slower than *Hpa*II-3. 3, Fragments obtained after cleavage of a *Hpa*II-digested sample of A-3 DNA with *Hae*III. The position of fragments known to come from the region of the polyoma physical map which contains *Hpa*II-3, -4 and -5 (B.E.G., unpublished) are indicated (*). One of the fragments from *Hpa*II-5 is extremely small, and has been run off this gel. 4, Fragments obtained after cleavage of a *Hpa*II-digested sample of D-50 DNA with *Hae*III. 5, Fragments obtained after cleavage of D-50 DNA with *Hae*III. 6, Fragments obtained after cleavage of A-3 DNA with *Hae*III. The position of fragments known to come from the region of the polyoma physical map which contains *Hpa*II-3, -4 and -5 are indicated (*). 7, Fragments 1–3 obtained after cleavage of A-3 DNA with *Hha*I. One cleavage site is known to occur in *Hpa*II-2, another in *Hpa*II-6 and the third in *Hpa*II-5 (Fig. 4). The two large fragments (about 46% and 42%) are not clearly separated on this gel. 8, The single product (about 17% genome length) obtained after cleavage of D-50 DNA with *Hha*I. (Some partial and undigested material can also be seen.)

Most defective DNA is shorter than infectious polyoma DNA[1-3], contains only restricted portions of the viral genome, and in some cases may also contain host sequences

covalently linked to viral sequences[4]. Interest in the isolation of pure defective DNA populations has been stimulated by the belief that such molecules, arising as they do from situations in which selective pressures are being exerted within cells, would be extremely useful both for studying virus–cell interactions and the evolution of the viral genome. A number of different defective molecules have recently been cloned in the presence of infectious wild-type polyoma (helper) molecules[3]. Molecules about 50% (designated D-50) the size of infectious polyoma DNA were purified from one clonal isolate and were found by heteroduplex studies to be homogeneous in size and to contain a single region of homology to about 18% of the sequences in polyoma DNA[5].

This report describes the sequences present in D-50, shows that other defective molecules present in the D-50 preparation contain the same sequences, and relates these sequences to those found around the origin of DNA replication in wild-type polyoma DNA.

Characterisation of defective species

A population of DNA molecules isolated from cells infected with a virus stock containing both polyoma D-50 molecules and wild type helper virus was found to contain molecules corresponding to about 34, 51, 68, 85 and 102% the size of the wild type polyoma genome (Fig. 1). The 51% species was found to be identical with the D-50 DNA previously analysed by electron microscopy[5]. The designation D-50 for this species will therefore continue to be used in this report. Heteroduplex studies showed the region of homology between D-50 and wild type DNA molecules to begin on the latter about 16% from the *Escherichia coli* RI restriction enzyme (*Eco*RI) single cleavage site[5]. On the physical map of polyoma DNA this site can lie in either restriction fragment *Hpa*II-6 or *Hpa*II-4 (ref. 6), (Fig. 4). To locate the homology region on the polyoma physical map and define the D-50 and related defective species more precisely, a restriction enzyme analysis was performed.

Cleavage with restriction enzymes

The resistance of D-50 molecules to cleavage by *Eco*RI restriction enzyme was shown earlier[3,5]. The other defective species from the same virus stock were also resistant to *Eco*RI. Moreover, all the species were resistant to cleavage with enzymes from *Haemophilus influenzae*, *Hin*III and *Hin*II, enzymes which each cleave wild type polyoma DNA into two fragments[6,7]. Cleavage of the defective DNAs with *Hha*I (from *H. haemolyticus*) produced only one fragment (about 17% wild type genome length) which was not similar in size to any of the three fragments produced from wild type DNA (B.E.G., unpublished). With *Hpa*II, the defective species were cleaved to two fragments only. One fragment (about 7.4%) was electrophoretically indistinguishable from *Hpa*II-5 of the wild type A-3 strain[8]. The other (about 10%) did not correspond to any of the known wild type *Hpa*II fragments. Some of these results are shown in Fig. 2 (columns 2 and 8).

Treatment of D-50 with *Hpa*II in incomplete digestion conditions produced one predominant partial digestion product, which corresponded in length to about 17% of the wild-type genome (Fig. 2, column 2).

No partial digestion products less than 17% were detected, nor any about 20% in length. These results suggest that in these DNAs there is a basic subunit (with two *Hpa*II cleavage sites) which is tandemly repeated either two, three, four, five or six times to produce the different defective species.

Fine structure mapping with *Hae*III

Two separate studies were made to locate more precisely on the physical map of polyoma DNA the sequences present in the defective molecules. In one, the defective DNAs and
Fig. 3 Autoradiograms of the two-dimensional fractional separation of pyrimidine tracts of some depurinated ^{32}P-labelled *Hpa*II fragments from wild type polyoma (A-3 strain) DNA and D-50 DNA. Depurinations and separations were carried out as described previously[9]: the first dimensional separation (from right to left) was carried out by electrophoresis on cellulose acetate strips at *p*H 3.5, and the second dimensional separation (from bottom to top) by homochromatography using homomix C[18]. Fractionation of pyrimidine tracts from the *Hpa*II-5 fragment from A-3 DNA (*a*), and the 7.4% *Hpa*II fragment from D-50 DNA (*b*). *a* and *b* can be seen, at least qualitatively, to be identical. Fractionation of pyrimidine tracts from the *Hpa*II-3 fragment from A-3 DNA (*c*), the *Hpa*II-4 fragment from A-3 DNA (*e*) and the 10% *Hpa*II fragment from D-50 DNA (*d*). All pyrimidine tracts present in *d* can be found in either *c* or *e*, although many tracts present in *c* and *e*, or in the entire wild type genome (not shown), are not found in *d*. Three large oligonucleotides (including oligo (T$_{7 \text{ or } 8}$), marked* in *c*) are characteristic of *Hpa*II-3 (B.E.G., unpublished) and can be seen in the D-50 fragment (*d*). The isoplith C$_3$T$_3$, marked (*) in *e*, is present in high yield both in *Hpa*II-4 and *d*.

their *Hpa*II cleavage products were treated with a restriction enzyme from *H. aegyptius* (*Hae*III) which cleaves polyoma wild-type DNA into approximately 23 fragments. The relationship between the *Hae*III fragments and the *Hpa*II fragments (used to construct the physical map of the polyoma DNA[6]) are known (B.E.G., unpublished). Therefore, *Hae*III can be used as an effective probe into the composition of the defective molecules. The cleavage by *Hae*III alone (Fig. 2, column 5) of the defective species gave one large fragment (about 13% wild type genome length) together with three small fragments, two of which could be identified as coming from *Hpa*II-3 and one from *Hpa*II-5. In wild-type DNA, these three small fragments join to form a continuous sequence which includes the *Hpa*II 3-5 junction. Treatment of the defective DNAs with both *Hae*III and *Hpa*II (Fig. 2, column 4) showed that the larger (13%) *Hae*III product could be cleaved into two fragments. One was identical with the fragment from wild type strain A-3 *Hpa*II-5 (adjacent to the *Hpa*II 4-5 junction) and the other slightly smaller than the fragment from wild-type *Hpa*II-4 normally found at the 4-5 junction.

Since one end of the latter fragment must lie at the *Hpa*II 4-5 junction and the other at the *Hae*III site in *Hpa*II-3, this fragment contains sequences from both *Hpa*II-3 and -4.

Fine structure mapping by depurination

Depurination fingerprints[9] of D-50, and the 85 and 102% species were made and found to be identical, thus supporting the relationship between these species. They were considerably less complicated than a depurination fingerprint of wild-type polyoma DNA. Pyrimidine tracts characteristic of wild type *Hpa*II fragments 1, 2, 6, 7 and 8 were found to be absent (B.E.G., unpublished). No pyrimidine tracts were found in the defective species which were not present in wild-type polyoma DNA.

In a second study, a comparison of the depurination fingerprint of the smaller *Hpa*II fragment from D-50 (about 7.4% wild type genome length) with *Hpa*II-5 from wild type DNA showed the two to be identical. The fingerprint of the larger *Hpa*II fragment (about 10% genome length) showed pyrimidine tracts characteristic of both wild type fragments *Hpa*II-3 and -4 (Fig. 3).

All the results are consistent with the defective DNAs being composed of tandemly repeating 17% units made up of all the viral sequences from polyoma *Hpa*II-5 (wild type A-3 strain) and part of the sequences from *Hpa*II-3 and -4. The results of the study on D-50 are summarised on a physical map, relative to wild type DNA[6], in Fig. 4.

Conclusions

One of the spontaneously arising defective species from polyoma virus has been cloned[3] and is here studied in detail. It has been shown to be made up of molecules containing two- to sixfold tandem repeats of a segment of approximately 17% of viral DNA. Restriction enzyme analysis, especially with *Hae*III, has defined the viral sequences in the 17% subunit as extending from *Hpa*II-3 through *Hpa*II-5 into *Hpa*II-4 on the polyoma physical map[6]. One of the *Hae*III fragments from the defective molecules is not identical with any of the wild type *Hae*III fragments and represents a fusion of sequences from *Hpa*II-3 and *Hpa*II-4. From these data the exact location of the ends of the defective subunit cannot be precisely placed on the physical map. The correlation of these studies with the size of the homology region observed by Robberson and Fried[5] suggests that most if not all of the sequences in the subunit are viral. Assuming only viral sequences to be present and knowing the order and approximate size of the *Hae*III fragments of the wild type DNA in this region it can be estimated that of the sequences in the 17% subunit, 18–27% come from *Hpa*II-3 and 42–53% from *Hpa*II-4. The results on the size of the defective subunit and its position on the physical map of polyoma DNA are in good agreement with the previous heteroduplex studies[5].

The segment of viral DNA present in D-50 and related defectives contains two of the biologically interesting markers so far located on the physical map of polyoma
Fig. 4 Diagrammatic representation of the homology region between D-50 DNA (circle) and *Eco*RI-treated wild type polyoma DNA (linear). Homology begins $16\pm2\%$ from the left end of wild-type DNA and extends to about 34% from the same end[5]. Numbers 1–8 on linear map show the order of the eight *Hpa*II fragments of polyoma DNA[8], and 5 and 3a+4b (circle) the order of the two *Hpa*II fragments of D-50 (and the defective DNAs related to it, as described in the text). *Hpa*II fragments 5 (about 7.4%) and 3a+4b (about 10%) make up the subunit (about 17%) found tandemly repeated three times in D-50 DNA, and two, four, five and six times in the other defective DNA related to D-50. The approximate site of the origin of DNA replication (○) is indicated[6]; note that this site is repeated three times in D-50 DNA. The cleavage sites of three other restriction enzymes, *Hin*III[6], *Hin*II and *Hha*I (B.E.G. unpublished) are indicated on the physical map of polyoma DNA.

DNA. One is the origin of DNA replication, which has been mapped around the *Hpa*II 3–5 junction at 71 ± 3 map units[6,19]. The other contains the 5′ ends of the early and late stable RNAs (transcribed from different DNA strands) which have been mapped in *Hpa*II-5 (ref. 10). It is interesting to note that the regions in which viral DNA synthesis terminates[6,19] and where the 3′ ends of viral messengers have been mapped[10,] have not been detected in these defective DNAs.

Molecules containing multiple origins of DNA synthesis might be expected to have selective advantages for replication over those molecules with a single origin. When apparently defective-free virus is grown at high multiplicity for a single cycle, defectives similar to those described here arise with high frequency. Although the size of the basic subunit seems to be variable, in most cases it seems to contain *Hpa*II-5 and thus can be detected by greater than unimolar equivalents of this fragment in the DNA[8]. Another clonal isolate containing molecules about 47% (D-47)[5] of the viral genome seems to contain a repeating unit of a 16% segment of viral DNA which includes *Hpa*II-5 (B.E.G. and M.F., unpublished). Similar molecules with repeated segments of sequences which contain the origin of DNA replication have also been detected in SV-40 (ref. 12) and PML virus[11,20] passaged at high multiplicities. The detection of repeated viral sequences in *Eco*RI resistant defective molecules from uncloned polyoma DNA preparations derived from high multiplicity passage may also contain repeats in this region[13]. Note that the type of defective defined here seems to be only one from among several types of defective DNAs that arise after passage of polyoma virus at high multiplicity.

It is not clear at present how D-50 and related DNAs arise. There are a number of mechanisms by which these defective DNAs can be generated. One possibility is that they are formed by errors in replication[8]. The study of other cloned defectives with basic subunits of different sizes will help clarify their origin. For instance, if the midpoint of all the different defective subunits were the same it would suggest that DNA synthesis proceeds bidirectionally at equal rates before the subunit is excised and ligated. On the other hand, if one end of the defective basic subunit were always at the same position on the physical map whereas the other end varied in position then unidirection replication for various lengths before excision and ligation might be suggested.

In this study, a correlation between the quantity of any species of defective DNA in the clonal isolate and the number of tandem repeats of the 17% subunit in that species has been observed (Fig. 1). Two explanations may

account for the greater abundance of the larger defective species. One would be the greater selective advantage for replication available to molecules with more origins of DNA synthesis. The other would be the possible difficulty of stable encapsidation (necessary for continued passage of the particular species) of the smaller DNA molecules.

The defective molecules containing multiple tandem sequence repeats are presumably derived from a common precursor of about 17% of the polyoma genome. We have not been successful in isolating this postulated small precursor molecule, but it would not be expected to be present in great quantities for reasons given above. The DNA isolation procedure used would also tend to discriminate against such a low molecular weight molecule. One of the interesting results from the present study is, however, the apparent uniformity of the repeating subunit. The results from a number of experiments suggest that there is little or no variation in the size of the *Hpa*II 7.4% fragment and if there is any variation in the size of the 10% *Hpa*II fragment, it is outside the scope of detection of the methods used. This suggests that D-50 and related molecules are derived from the subunit by recombination events.

Further, it is interesting to note that DNA derived from virus stocks produced from purified D-50 molecules and added helper DNA generated all the species of the multiple repeat defectives found in the parental population (Fig. 1). This generation of both larger and smaller related defective molecules from the D-50 species suggests that intramolecular and possibly intermolecular recombination processes can occur. Moreover, in the DNA produced from virus stocks made from the purified D-50 molecules the D-50 species is seen to be present in greater yields than the 68% species (Fig. 1*a* and *b*), whereas in the parental population the reverse is true (Fig. 1*c*). This seems to mitigate against the rolling circle model of DNA replication[22] as a mechanism for the generation of the related defectives, as this type of replication would not show any preference for the production of D-50 species over the 68% species.

We thank Drs R. Roberts, R. Old and R. Kamen for restriction enzymes, and Mrs M. Griffiths for assistance.

Implications for theories of anaesthesia of antagonism between anaesthetic and non-anaesthetic steroids

C. D. Richards & T. R. Hesketh

National Institute for Medical Research, Mill Hill, London NW7 1AA, and Department of Biochemistry, University of Cambridge, Tennis Court Road, Cambridge CB2 1QW, UK

The non-anaesthetic steroid $\Delta16$-alphaxalone antagonises the depressant action of the anaesthetic steroid alphaxalone on synaptic transmission. This antagonism is not predicted by classical theories of anaesthesia and therefore poses fundamental questions about the molecular basis of anaesthesia.

IT is now widely accepted that there is a good correlation between the anaesthetic potency of a substance and its lipid solubility[1-4]. This correlation has led to a number of hypotheses of anaesthetic action, notably the Meyer–Overton rule of lipid solubility[5] and the critical volume hypothesis of Mullins[6]. These hypotheses state that anaesthesia occurs whenever a certain critical concentration or a critical molar volume of an inert substance is achieved in the neuronal membranes. These theories have a serious weakness, however, in that they concentrate attention on substances that are both lipid-soluble and anaesthetic, and ignore those that are lipid-soluble but have no anaesthetic properties.

Some steroids possess anaesthetic properties whereas others do not[7]. Systematic examination of some 5α-pregnanes has shown that steroids having the same functional groups could be either anaesthetic or non-anaesthetic according to their precise structure[8,9]. These observations are not easily reconciled with the hypotheses of anaesthetic action based on lipid solubility, as the steroids are themselves lipids. It could be argued that the non-anaesthetic steroids fail to produce general anaesthesia simply because they do not reach the brain in sufficient quantity to cause anaesthesia. It follows from this argument that, if we could apply 'non-anaesthetic' steroids directly to the nerve cells of the brain, we should be able to reveal their anaesthetic properties.

One preparation suitable for testing this idea is the isolated olfactory cortex of the guinea pig[10,11]. A number of general anaesthetics depress excitatory synaptic transmission in this preparation at concentrations likely to be found in the brain during anaesthesia[12-15]. If we could show that anaesthetic steroids also depressed excitatory synaptic transmission in this preparation, and that non-anaesthetic steroids did not, then we could conclude that either the non-anaesthetic steroids cannot penetrate synaptic membranes or that they can, but fail to alter normal membrane function. In either event some factor in addition to lipid solubility would be required to explain such results.

In the work presented here, we have examined the pharmacological action of two closely related steroids on synaptic transmission in the olfactory cortex. One of the compounds,

3α-hydroxy-5α-pregnane-11,20-dione (alphaxalone) is a powerful anaesthetic and is the main active component in the clinically used anaesthetic Althesin. The other, 3α-hydroxy-5α-pregnan-16-ene-11,20-dione ($\Delta16$-alphaxalone) is non-anaesthetic[9]. The structures of these two substances (Fig. 1) differ only by a double bond in the D ring of the steroid nucleus.

Isolated preparations of guinea pig olfactory cortex have been shown to generate stable and characteristic field potentials in response to electrical stimulation of the lateral olfactory tract (LOT)[11-15]. If a recording electrode is placed on the pial surface of the prepiriform cortex close to the LOT and a pulse is subsequently applied to the anterior end of the LOT, a complex wave form can be recorded (see Fig. 2). This comprises an initial wave—the compound action potential caused by activity in the LOT fibres—followed by a negative wave (the population excitatory postsynaptic potential, or population e.p.s.p.) which has been identified as the field potential arising from the synchronous depolarisation of the apical dendrites of many of the cortical neurones. If the population e.p.s.p. is sufficiently large, a number of positive peaks may be superimposed on it. These peaks reflect the synchronous discharge of the cortical cells in response to the population e.p.s.p. and are called population spikes[17] (see Fig. 2). (If the recording electrode is placed in the pyramidal cell layer instead of on the cortical surface, a similar potential can be recorded, but of reversed polarity[18] (Fig. 3).) The amplitude of the population e.p.s.p. is proportional to the number of active synapses and to the degree of depolarisation of each postsynaptic site; the area of the population spikes is proportional to the number of discharging cortical cells. In this paper we have taken the amplitude

Fig. 1 Structural formulae of steroids used. *a*, Alphaxalone; *b*, $\Delta16$-alphaxalone.
Fig. 2 Depressant action of alphax-alone on the evoked potentials of the olfactory cortex. *A*, Time course of experiment. Arrowed line under black bar indicates period during which CSF containing liposomes was superfusing the preparation. Black bar indicates period of exposure to alphaxalone (5×10^{-5} M) *B*, Sample records of four to six superimposed sweeps taken at various times during the experiment. *a*, Control, *b*, 6 min in liposomes; *c*, 5 min in alphaxalone; *d*, 10 min in alphaxalone; *e*, 10 min after alphax-alone; *f*, recovery. Alphaxalone was administered as the steroid component of liposomes. Egg yolk lecithin was dissolved in chloroform–methanol (2:1 v/v) together with the steroid in a molar ratio of 1:1. The solutions were evaporated to dryness under nitrogen and kept under vacuum (10^{-3} mmHg) for 1–4 h to remove residual traces of solvent. Artificial CSF (refs 12–14) was then added to yield a final concentration of 50 μM phospholipid. Solutions at 4 °C were then subjected to ultrasonic dispersion for 2–5 min using an MSE probe sonicator to suspend the phospholipid as small vesicles.

of the population e.p.s.p. at a fixed latency from the stimulus as our chief measure of postsynaptic activity[12–15].

As steroids are very hydrophobic substances, they are very sparingly soluble in water. Clinically, they are administered as micelles with Cremaphor EL (a polyoxyethylated castor oil) as the carrier[16] but Cremaphor was toxic to our isolated preparations. To overcome this, we applied alphaxalone as the steroid component of lecithin vesicles (liposomes) suspended in the artificial cerebrospinal fluid (CSF) that superfused the isolated cortical tissue. This method of applying the steroids has proved quite satisfactory.

When liposomes containing cholesterol, or lacking a steroid component, were added to the artificial CSF that superfused the isolated cortical tissue, little change was seen in the evoked potentials (Figs 2 and 3). If the superfusing artificial CSF containing lecithin liposomes was changed for one containing liposomes with alphaxalone in a 1:1 molar ratio with the phospholipid (to give a final concentration of 5×10^{-5} M alphaxalone in the artificial CSF) then the population e.p.s.p. and population spikes became depressed but the LOT compound action potential was not affected (Fig. 2). Provided the tissue was not exposed to the alphaxalone for long periods (greater than 20 min) the depression of the population e.p.s.p. and population spike rapidly reversed when artificial CSF containing lecithin liposomes replaced that containing alphaxalone-loaded liposomes. Thus, alphaxalone depressed the population e.p.s.p. and population spikes without blocking nerve impulse conduction in the afferent LOT fibres. The depression of the population e.p.s.p., however, produced by a given dose of alphaxalone varied rather widely, in the range 25–100% for a concentration of 5×10^{-5} M in the CSF, although it generally lay between 30 and 60% (Table 1). As with other general anaesthetics[12–15] this depression occurred at concentrations of alphaxalone likely to be found in the brain during anaesthesia. (An anaesthetic dose of alphaxalone has been found to be approximately 3 mg kg⁻¹ for a number of species[16]. As the anaesthetic must reach the brain cells by way of the extracellular fluid which accounts for 20–30% of the total body weight[19], 3 mg kg⁻¹ alphaxalone given intravenously will have a maximum concentration in the extracellular space of 3×10^{-5} to 5×10^{-5} M (ref. 12).)

If the liposomes superfusing the tissue contained not alphaxalone but Δ16-alphaxalone, a very much smaller depression of

the population e.p.s.p. of about 10–15% was seen (Table 1). Furthermore, increasing the duration of the superfusion by Δ16-alphaxalone beyond the normal 10 min period (up to a maximum of 45 min) did not further increase the depression of the population e.p.s.p.

These results correlate well with the effects of these steroids *in vivo;* the anaesthetic steroid alphaxalone depresses the population e.p.s.p. by 30–60%, whereas the non-anaesthetic steroid Δ16-alphaxalone has little depressant action. These results suggest that both steroids can penetrate the synaptic membranes, as they both depress the population e.p.s.p., but, unlike alphaxalone, Δ16-alphaxalone is not able to disrupt synaptic transmission to any great extent.

Antagonism of depressant action of alphaxalone by Δ16-alphaxalone

After an experiment in which the depressant action of Δ16-alphaxalone had been tested, we exposed the same preparation to alphaxalone and discovered that alphaxalone had only a slight depressant action. The preparation was left in artificial CSF for 3 h and was then exposed again to alphaxalone. After this time the preparation regained its sensitivity to alphaxalone (Fig. 3). This antagonism of the depressant action of alphaxalone by Δ16-alphaxalone has now been confirmed in ten separate experiments using two different samples of alphaxalone and Δ16-alphaxalone, and three different samples of lecithin (Table 1). Of the ten experiments, four showed almost complete reversal of the Δ16-alphaxalone block 1–3 h after exposure to Δ16-alphaxalone, two showed a partial reversal and in the remaining four experiments, the depressant action of alphaxalone was blocked throughout the experiment (up to 3 h).

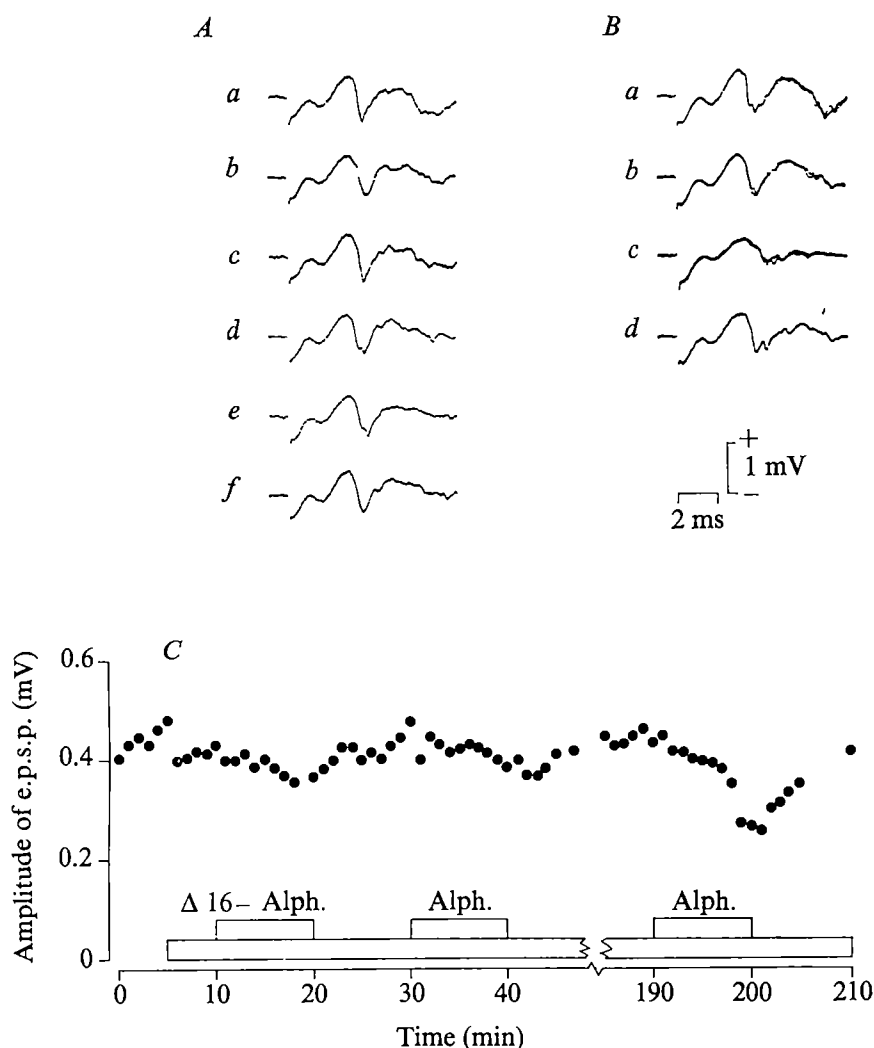
If a preparation had first been exposed to alphaxalone before treatment with Δ16-alphaxalone, subsequent exposures to alphaxalone generally caused the same depression of the e.p.s.p. as that seen initially. To reveal the antagonism of the depressant action of alphaxalone by Δ16-alphaxalone it was necessary to expose the tissue to Δ16-alphaxalone—before making any test for the depressant action of alphaxalone. For this reason the depressant action of the alphaxalone-containing liposomes was checked in a parallel experiment on a preparation not pretreated with Δ16-alphaxalone. Both the control experiments and those demonstrating the antagonism were performed on the same day to eliminate variation in the release of alphaxalone


Fig. 3 Action of Δ16-alphaxalone on evoked potentials of olfactory cortex. *A* and *B*, Sample records taken from the cell body region of the slice at various times during the experiment shown below. *A*, Records taken in the first 45 min of the experiment. *a*, Control; *b*, Δ16-alphaxalone; *c*, control 2; *d*, 5 min in alphaxalone; *e*, 10 min in alphaxalone; *f*, recovery. *B*, Records taken after 185 min. *a*, Control 3; *b*, 5 min in alphaxalone; *c*, 10 min in alphaxaone; *d*, recovery. *C*, Time course of the experiment. Δ16-alphaxalone (5 × 10⁻⁵ M) had little depressant effect. Initial exposure to alphaxalone (5 × 10⁻⁵ M) showed only slight depressant activity but a subsequent exposure to alphaxalone (approximately 3 h after the exposure to Δ16-alphaxalone) markedly depressed the population e.p.s.p. Lecithin (10⁻⁴ M) in CSF after 5 min for duration of experiment

from liposomes as a result of ageing or the formation of lysolecithin. One example of these paired experiments can be seen in Fig. 4.

Nature of the antagonism

The antagonism of the depressant action of alphaxalone by Δ16-alphaxalone could be the result of one of two processess either Δ16-alphaxalone prevents the release of alphaxalone from the liposomes (that is, it is an artefact of the method of application) or it antagonises the depressant action of alphaxalone on some process involved in synaptic transmission.

As the antagonistic effects of Δ16-alphaxalone on the depression of the e.p.s.p. by alphaxalone could persist for several hours, it seems unlikely that small amounts of Δ16-alphaxalone were merely reducing the release of alphaxalone from the phospholipid vesicles. This argument is further supported by the observation that, following a short exposure (5 min) to Δ16-alphaxalone, one preparation did not exhibit resistance to the

depressant action of alphaxalone. Moreover, the antagonism did not develop if a preparation had first been exposed to alphaxalone before treatment with Δ16-alphaxalone. These observations strongly suggest that the antagonism is a genuine pharmacological event.

Given that Δ16-alphaxalone antagonises the depressant action of alphaxalone by some biological mechanism, there are four ways in which this could be brought about. First, Δ16-alphaxalone could prevent alphaxalone penetrating the synaptic membranes. Second, Δ16-alphaxalone could be acting as a competitive antagonist at some specific site or sites. Third, as synaptic transmission is a multistage process, Δ16-alphaxalone and alphaxalone could act at different sites but have opposing actions which tend to cancel. Fourth, Δ16-alphaxalone could desensitise the preparation to alphaxalone.

Of these four possibilities, the first two seem the most plausible but we have no evidence that enables us to distinguish between them. The third possibility seems unlikely because

Table 1 Depression of population e p.s p. at the end of a 10-min exposure to 50 μM alphaxalone or 50 μM Δ16-alphaxalone

Drug	Pretreatment	Depression of population e.p.s.p. (% control)			No. of experiments
		Mean	± s.e.m.	Range	
Δ16-alphaxalone	None	14.8	± 2.5%	0–25%	9
Alphaxalone	None	45.7	± 5.7%	25–100%	12
Alphaxalone (10 min after pretreatment)	(20 min in Δ16-alphaxalone)	9.4	± 3.26%	0–35%	10

O, Depression produced in an untreated preparation; ●, block of alphaxalone-induced depression 12 min after exposure to Δ16-alphaxalone; ▲, recovery of sensitivity to alphaxalone 160 min after exposure to Δ16-alphaxalone. Bar, alphaxalone $(5 \times 10^{-5}$ M) exposure.

Δ16-alphaxalone and alphaxalone show qualitatively similar effects on the synaptic potentials. Furthermore, the antagonism outlasts the depressant action of Δ16-alphaxalone (Fig. 3). The fourth possibility is also unlikely as Δ16-alphaxalone does not antagonise the depressant action of alphaxalone in preparations which had been exposed to alphaxalone before treatment with Δ16-alphaxalone. Further indirect evidence against a desensitisation hypothesis comes from experiments on mice, in which it has been shown that successive injections of alphaxalone result in a slight increase in the sleep time resulting from a given dose of anaesthetic[20].

It is possible that the antagonism between these steroids reflects the existence of specific anaesthetic receptors for steroids, especially as the structure–activity relationships for anaesthetic potency are so well defined[8,9]. No firm answer can however, be given at present, but it should be noted that both 5α-and 5β-pregnanes may be anaesthetic in spite of the marked difference in the shape of the steroid nucleus in these two series. Furthermore, steroids are very lipid-soluble and show some of the nonspecific membrane effects of other general anaesthetics[4]— for example, they protect erythrocytes from lysis[21], presumably by expanding the membranes[4].

Implications for theories of anaesthesia

Hypotheses of anaesthetic action based on simple solubility models, such as the Meyer–Overton lipid solubility rule of anaesthesia[5] or the critical volume hypothesis of Mullins[6], imply that all anaesthetics act in the same region. This has led to the formulation of the unitary hypothesis of anaesthetic action, in which it is asssumed that general anaesthetics produce their effects by simple physicochemical interactions with hydrophobic regions of the cellular membranes, and not by interaction with specific sites[22]. It is implicit in all three hypotheses that the effects of two lipophilic compounds should be synergistic, not antagonistic[23], and this has indeed been shown for several pairs of compounds[24,25]. One striking example is the synergism of tetrahydrocannabinol and diethyl ether. Although tetrahydrocannabinol is highly lipophilic it is not an anaesthetic, yet when given intravenously to mice it reduces the amount of ether required to abolish the righting reflex[26].

One hypothesis of anaesthetic action does predict the existence of antagonism between different classes of anaesthetic. This is the degenerate perturbation hypothesis proposed by Metcalfe *et al.*[27] to account for the local anaesthetic action of a wide variety of organic compounds. This hypothesis is based on the opposing actions, on model membrane systems, of small molecules such as benzyl alcohol and large rigid molecules, such as androstane; benzyl alcohol increases and androstane decreases the fluidity of phospholipid bilayers[28-30]. Although

clinical concentrations of some general anaesthetics (halothane and methoxyflurane) have been shown to fluidise phospholipid bilayers[31], preliminary results with electron spin resonance techniques have shown no change in membrane fluidity when either alphaxalone or Δ16-alphaxalone are added to a phospholipid bilayer (T.R.H., unpublished). This suggests that the antagonism of the depressant action of alphaxalone by Δ16-alphaxalone is not mediated by generalised perturbations of membrane structure and presumably depends on more specific interactions within the synaptic membranes.

The antagonism of the effects of alphaxalone by Δ16-alphaxalone cannot be accommodated by any of the hypotheses of anaesthetic action mentioned above and we must, therefore, conclude that they do not apply to anaesthesia induced by steroids. It remains to be seen whether substances other than Δ16-alphaxalone can antagonise the depressant action of alphaxalone and whether Δ16-alphaxalone can antagonise the action of other general anaesthetics on synaptic transmission.

We thank our colleagues for reading and commenting on the manuscript, and Mr B. Davis and Dr G. H. Phillipps of Glaxo Research Ltd for the steroids and for discussion.

Isolation of polar insertion mutants and the direction of transcription of ribosomal protein genes in *E. coli*

S. R. Jaskunas, L. Lindahl & M. Nomura

Institute for Enzyme Research, Departments of Genetics and Biochemistry, University of Wisconsin, Wisconsin 53706

Transcription of ribosomal protein genes in the str-spc *region in* Escherichia coli *seems to be exclusively anti-clockwise. Insertion mutations in this region inactivate many but not all distal ribosomal protein genes. Thus, there seems to be more than one transcriptional unit for the ribosomal protein genes in this region.*

MANY ribosomal protein (r-protein) genes in *Escherichia coli* are clustered at the *str-spc* region of the chromosome (see ref. 1 for review). Little is known about the organisation of these genes, however, or the mechanism of the regulation of their expression. Recent isolation of λ transducing phages carrying many r-protein genes from this region[2] has made it possible to study these problems in detail. Here we report the isolation of insertion mutations of the transducing phage λ*spc*1 that inactivate the expression of many, but not all, of the r-protein genes carried by this phage. In this connection, we have reinvestigated the direction of transcription of r-protein genes in the *str-spc* region. We have found that, contrary to the previous suggestion[3], the direction of transcription is anti-clockwise on the *E. coli* genetic map. The inactivated genes in our mutants are distal to the sites of the insertion mutations, and may belong to a single transcriptional unit.

Insertion mutations affecting r-protein genes

The λ*spc*1 phage carries a *spc*^{s} gene as well as *aroE*$^+$ and *trkA*$^+$ genes[2]. Bacterial strains carrying the *spc*^{r} allele become spectinomycin-sensitive (Spc-S) when they are lysogenised with λ*spc*1, because *spc*^{s} is dominant over the *spc*^{r} allele[21]. The lysogen from which we isolated Spc-R mutants had the following relevant chromosomal genetic markers: *KdpABC5*, *trkA*401, *spc*^{r}, *str*^{r}, *fus*^{r}, *recA*; and carried λ*spc*1 and a helper phage λ*c*1857*S*7. Thus this strain is diploid for the *spc* gene (*spc*^{s}/*spc*^{r}) and is phenotypically Spc-S. The selection of Spc-R mutants was done on tryptone-yeast extract agar plates containing Spc (100 μg ml^{-1}). This medium has a low concentration of potassium and does not enable growth of *trkA* mutants. Thus Spc-R colonies selected on this medium must have retained the *trkA*$^+$ gene carried by the λ*spc*1 phage. The Spc-R phenotype presumably resulted from some mutation that inactivated or altered the *spc*^{s} gene on the phage.

Transducing phages were then isolated from these Spc-R mutants and characterised. Out of 20 independently isolated Spc-R colonies the transducing phage could be recovered from 18, and 14 of them carried an insertion of a small piece of DNA in the phage (see below). Thus the inactivation of the *spc*^{s} gene in these 14 mutants seemed to be a result of an insertion. Two such mutants, λ*spc*1–I15 and λ*spc*1–I16, were studied in detail.

To examine the expression of other r-protein genes carried

by these mutant phages, we have measured the stimulation of r-protein synthesis in ultraviolet-irradiated *E. coli* cells after infection by the mutant phages and compared the stimulation with that caused by the parental transducing phage λ*spc*1 (Table 1).

The parent λ*spc*1 stimulates the synthesis of about 20 r-proteins (ref. 2 and Table 1). The strong stimulation of the synthesis of proteins S4, S11, S13 and L17 (see group I in Table 1) was also observed following infection by the mutant phages λ*spc*1–I15 and λ*spc*1–I16. The stimulation of the synthesis of many other r-proteins including S5, which is coded for by the *spc*^{s} gene (group II in Table 1), was, however, greatly reduced or abolished with λ*spc*1–I16. The reduction in the stimulation of the synthesis of these proteins was in general smaller with λ*spc*1–I15, but was still significant compared with the group I proteins. There are some proteins (group III in Table 1), whose synthesis was weakly stimulated by λ*spc*1 phage, or which were difficult to classify into group I or II with respect to the susceptibility of their synthesis to the insertion mutations (see the legend to Table 1).

It should be noted that the effect of the I15 insertion on the stimulation of the synthesis of group II proteins is not uniform. In particular, the stimulation of the synthesis of L24 was almost completely abolished by the I15 insertion. It is possible that the I15 insertion is within the gene for L24.

We have also done similar experiments with several other insertion mutants of λ*spc*1. As described below, the size of inserted DNA in λ*spc*1–I15 is different from that in λ*spc*1–I16. All other insertion mutants could be classified into two classes with respect to the size of inserted DNA, one about the same as that of I15, and the other about the same as that of I16. It was observed that other insertion mutants of "I16 type", like I16 itself, showed marked effects on the synthesis of the group II proteins, but not on that of the group I proteins. Conversely, the effects observed by mutants of "I15 type" were in general similar to those observed with λ*spc*1–I15: that is, partial inactivation of many or all of group II protein genes and weak or no inactivation of group I protein genes.

These data indicate that there are at least two classes of r-protein genes on λ*spc*1 whose expression is controlled separately. The insertion mutations studied here seem to appreciably affect one class (group II) but not the other(s) (group I). The weak inactivation found for group I proteins and the difference between the two experiments reported in Table 1 may be a result of slight differences in the multiplicity of infection (see legend to Table 1).

It should be noted that we have proved only that the structural genes for S4, S5, S8, S11, S13 and S14 are carried by λ*spc*1 since these proteins are made in our DNA-dependent *in vitro* protein synthesising system using λ*spc*1 DNA as template[2]. It is highly likely, however, that the structural genes for most of the other proteins in groups I and II are also carried by

Table 1 Stimulation of the synthesis of individual r-proteins by λspc1, λspc1–I15 (I15) and λspc1–I16 (I16)

E. coli cells prelabelled with ¹⁴C-leucine were irradiated with ultraviolet light and infected with phages as previously described[2] except that the ultraviolet-sensitive bacterial strain was a λpapa lysogen of strain 159 (ref. 12). The ³H-leucine was added 30 min after phage infection and the incorporation was stopped after 10 min. The cells were lysed and proteins were extracted and separated by two-dimensional gel electrophoresis[13]. The ³H/¹⁴C ratio of each r-protein spot, except S1 and L31, was determined. Details of the procedures were described previously[2,10,11]. The data are shown only for the proteins whose synthesis was previously found to be stimulated by λspc1 Synthesis of other proteins was not significantly stimulated by λspc1 compared with the control phage λc1857S7 (λS7). The proteins are classified into groups I and II as described in the text. Group III includes proteins whose synthesis was only weakly stimulated (S3, S7, L13) or whose classification with respect to groups I and II is not clear (L22, L23). The pattern observed with L22 and L23 appears similar to that observed for group I proteins. In the case of L11, the apparent stimulation of its synthesis may be due to contamination of the L11 spot by S5. Concerning a weak reduction by the 116 insertion in the stimulation of the synthesis of group I proteins, we note that stimulation of the synthesis of r-proteins by the transducing phages depends on the multiplicity of infection In the present experiments, the same 'multiplicity' was used, as judged by the absorbance values of the various phage preparations at 260 nm. This corresponds to multiplicity 5 of infectious λS7. Thus, the possible presence of some inactive phage particles in the λspc1–I16 preparation may explain the weak reduction observed in the stimulation of the synthesis of the group I proteins. The slight difference between the two experiments may also be explained on the same basis.
*Similar experiments were done except that the bacterial strain used as a host was a non-lysogenic and ultraviolet-sensitive strain (NO1261)[2]. The values obtained are shown in parentheses.
†Proteins S9 and S11 co-electrophorese in the two-dimensional gel. But, S11 can be made *in vitro* using λspc1 DNA as template but not S9 (ref. 2). Thus, the stimulation of the incorporation of ³H-leucine into this spot is probably a result of the synthesis of S11.

λspc1. Most of these proteins are clearly separated from other proteins in the two-dimensional electrophoresis system used to determine synthesis of r-proteins in the irradiated cells and their synthesis seems to be strongly stimulated by λspc1 infection. Thus this stimulation probably reflects the presence of the structural gene on λspc1.

Physical mapping of insertion mutations

The structure of λspc1, as well as other transducing phages that we have isolated, has been studied by the use of DNA restriction endonucleases (such as EcoRI) and by electron microscopic analysis of various heteroduplexes (Fiandt, Szybalski, Blattner, Lindahl, Jaskunas and Nomura, in preparation). Figure 1 shows the position of various bacterial genes on these transducing phages and the position of the EcoRI sensitive sites on the λspc1 genome.

Both λspc1–I15 and λspc1–I16 had increased phage particle densities (1.489 and 1.491g ml⁻¹, respectively) relative to the parent λspc1 (1.486g ml⁻¹). These increased densities originally suggested that the inactivation of the *spc*ˢ gene on these phages was the result of an insertion. Furthermore, EcoRI digestion of the DNAs from both λspc1–I15 and λspc1–I16 showed a fragment pattern identical to that from λspc1 except that the 17% fragment from λspc1 was replaced by larger fragments in the mutants. These results indicate that the insertions are

in the original 17% fragment which contains the junction of bacterial and λ DNA ("*coli*-λ junction").

The precise position of the insertions as well as the size of the inserted DNAs was determined by heteroduplex analysis. Examples are shown in Fig. 2. In these experiments, the heteroduplexes formed between the mutant (or parent) DNAs and the DNA from λfus2 were examined. λfus2 is a transducing phage carrying the genes *aroE*, *trkA*, *spcA*, *strA*, and *fus*, as well as approximately 28 other r-protein genes (our unpublished experiments, cited in ref. 2). The DNA in λspc1 up to the *coli*-λ junction is homologous to DNA in λfus2 (see Fig. 1). The positions of the insertions obtained from the heteroduplex experiments are indicated in Fig. 1. The I16 insertion was found 270±30 base pairs left of the *coli*-λ junction and the I15 insertion was found 850±40 base pairs left of the junction. Thus, both insertions are in the bacterial DNA. Since the DNA between either insertion and the *coli*-λ junction can code for only one to three r-proteins, we conclude that most or all of the inactivated genes are to the left of the insertions. Independent measurements of the distance between the two insertion sites in the heteroduplex from λspc1–I15 and λspc1–I16 (Fig. 2d) gave the value 610±60 base pairs, which agrees with the calculated value, 580±50.

The sizes of the inserted DNAs were measured and found to be 680±70 base pairs in λspc1–I15 and 1,160±110 base pairs in λspc1–I16. Thus the sizes of these two inserted DNAs
Fig. 1 The structure of λ, λ*fus2* and λ*spc1*. DNA from the λ genome is hatched. Arrows under the λ*spc1* chromosome show the *Eco*RI sensitive sites which produce seven DNA fragments. The size of these fragments is indicated in % λ units. The *str* gene is present in λ*fus2*, but not in λ*spc1*. The structure of λ*fus2* and λ*spc1* is based on the experiments by M. Fiandt, W. Szybalski, F. Blattner, L. Lindahl, R. Jaskunas and M. Nomura (in preparation). Two thick arrows under the λ chromosome indicate the leftwards transcription from the P_L promoter and rightwards transcription from the P_R promoter, respectively. The location of genes for S4, S11 and S13 as well as that of the insertion mutations, I15 and I16, is indicated.

are similar to the sizes of the well-studied insertion DNAs, IS1 (750 to 870 base pairs) and IS2 (1,170 to 1,420 base pairs), respectively[4,5]. The slight difference between our value for I15 and the published values for IS1 is probably not significant.

Direction of r-protein gene transcription at the *str-spc* region

λ*spc1* phage carries about 20 r-protein genes. The data described above show that the insertion of small DNA fragments depresses the expression of many r-protein genes located left of the site of the insertion (compare Fig. 1). The simplest interpretation of the results is that these inactivated genes belong to one transcriptional unit and that the direction of transcription is from right to left in Fig. 1.

Previous experiments suggested that the direction of the transcription of r-protein genes in this region is from *spc* to *str* (ref. 3 and other experiments cited in ref. 1). Since that is opposite to the above expectation, we have reinvestigated the direction of the transcription by determining which strands of λ*spc1* and λ*fus2* hybridise with the r-protein messages for this region.

First, we separated the strands of DNA from λ*trkA*, λ*spc1* and λ*fus2* and determined which strands would hybridise 'leftwards' transcripts and which would hybridise 'rightwards' transcripts. λ*trkA* is a control phage which has only the *aroE-trkA* end of λ*spc1* and λ*fus2*. It does not seem to code

for any r-proteins[2]. For λ*trkA* and λ*spc1*, identification of the polarity of the separated strands was done with purified λ-*l* and λ-*r* transcripts. We found that the 'heavy' strand of λ*trkA* hybridised with the λ-*r* transcript while the 'light' strand of λ*spc1* hybridised with this transcript (Table 2). This method could not be used to determine the polarity of the λ*fus2* strands since they did not hybridise a significant fraction of the standard λ transcripts, presumably because this phage contains only a small fraction (7%) of the λ genome. We therefore used the *in vitro* transcript from the 5% *Eco*RI fragment of λ*spc1* (compare Fig. 1). This transcript ("5% transcript") contained mainly 'leftwards' transcript since it hybridised primarily with the λ*spc1-l* strand (Table 2). λ*fus2* also contains the 5% *Eco*RI fragment and we found that its 'heavy' strand hybridised with the 5% transcript establishing it as the λ*fus2-l* strand (Table 2).

It was previously shown that the *in vivo* synthesised RNA which hybridises to λ*spc1* DNA is almost exclusively r-protein mRNA and its major fraction is homologous to the bacterial DNA where the genes affected by I15 and I16 are located (P. Dennis and M. Nomura, unpublished). Data presented in Fig. 3 show that *in vivo* synthesised mRNA hybridised with the *l*-strands of λ*spc1* and λ*fus2* but not with their *r*-strands. We conclude that *in vivo* transcription of the r-protein genes in the *str-spc* region seems to be exclusively leftwards, that is, in the direction of *str* to *spc*.

Table 2 Hybridisation of *in vitro* transcribed RNA to separated DNA strands of transducing phages

Experiment No.	RNA Type	Input c.p.m.	λ H	λ L	λtrkA H	λtrkA L	λspc1 H	λspc1 L	λfus2 H	λfus2 L

Binding to filters in the absence of DNA [(1) 28 c.p.m.; (2) 22 c.p.m.; (3) 26 c.p.m.; (4) 30 c.p.m.] has been subtracted. Preparation of transcripts from the λ-strands: ^{3}H-labelled transcripts from λ DNA were made in a system with the following composition: 10 mM Tris-HCl (*p*H 7.9), 10 mM MgCl$_2$, 0.1 mM EDTA, 0.1 mM dithiothreitol, 0.5 mM K-phosphate, 60 mM KCl, 6% glycerol, 0.6 mM ^{3}H-UTP (1.3 Ci mmol^{-1}), 0.5 mM CTP, 0.5 mM ATP, 0.5 mM GTP, 11 μg ml^{-1} λ DNA and 240 μg ml^{-1} protein of an RNA polymerase preparation, which is approximately 50% pure[14]. The mixture was incubated at 37 °C for 45 min. The reaction was terminated by chilling to 0 °C, 200 μg tRNA was added as carrier and nucleic acids purified by the phenol method. From this preparation 'leftwards' (λ-*l*) and 'rightwards' (λ-*r*) transcripts were purified by preparative hybridisation to λ-L and λ-H strands essentially as described by Bøvre *et al.*[15]. "5% transcript" was prepared in a DNA-dependent protein synthesising system as described previously[14], except that RNA was labelled (with 8.5 Ci mmol^{-1} ^{3}H-UTP) rather than protein. The template used was a 5% fragment of λ*spc1* DNA prepared by *Eco*RI digestion (see Fig. 1). Its molecular weight is about 1.4×10^6 and it codes for the r-proteins S4, S11 and S13 (Lindahl, Zengel and Nomura, in preparation). λ*spc1* transcript was prepared using λ*spc1* DNA as a template according to the method used for the λ transcripts (see above). Separation of strands was performed by annealing with poly(U,G) and isopycnic CsCl centrifugation as previously described[15,18]. Liquid hybridisation was performed in 2 × SSC using a large excess of DNA. Samples were incubated at 67 °C for 4–6 h and collected on Millipore HAWP nitrocellulose filters. Each filter was washed with 50 ml 2 × SSC. The filters were then incubated in 20 μg pancreatic and 2.5 units T1 ribonucleases ml^{-1} in 2 × SSC (1.5 ml per filter) for 1 h at 37 °C. Finally the filters were washed twice in 2 × SSC (10 ml per filter), dried, and the radioactivity bound to each filter was measured. SSC contains 0.15 M NaCl, 0.015 M Na citrate, *p*H 7.2.

*DNA strand H and L designate separated strands which were located at heavier and lighter density positions, respectively, in the isopycnic CsCl centrifugation after annealing with poly(U,G).
Fig. 2 Electron micrographs of heteroduplex DNA molecules. *a*, λ*spc*1 and λ*fus*2 DNA; *b*, λ*spc*1–I16 and λ*fus*2 DNA; *c*, λ*spc*1–I15 and λ*fus*2 DNA; *d*, λ*spc*1–I16 and λ*spc*1–I15 DNA. Both phage PM2 DNA (9,500 base pairs; refs 19 and 20 and W. Szybalski, personal communication) and ΦX174 DNA (5,250 base pairs; ref. 20) were added as references for length measurements. In *a* and *b*, one PM2 DNA molecule overlaps on the heteroduplex molecules. The tracings of each heteroduplex are shown together with the electron micrographs. Heavy lines are duplex regions, and light lines are single-strand regions. Several key positions are indicated as follows: A, the left end of the heteroduplex molecule (compare Fig. 1); B, the position of the right *coli*-λ junction in λ*spc*1; C, the position of the right *coli*-λ junction in λ*fus*2; D, the right end of the heteroduplex molecule; I, the position of insertion (I15 or I16). The method for preparation of heteroduplexes and for electron microscopy was according to ref. 16. The lengths of double strand DNA regions were measured using PM2 DNA as a reference. The lengths of single strand DNA regions were measured using ΦX174 DNA as a reference, but in some experiments, PM2 DNA was used as a reference. No significant difference was observed between the values obtained with the two methods.

Both λ*spc*1 DNA and its 5% *Eco*RI fragment code for r-proteins in our DNA-dependent protein synthesising system. We found that the *in vitro* transcripts from these DNAs also hybridised predominantly to the *l*-strand of λ*spc*1 DNA (Table 2). Since the 5% fragment seems to contain only r-protein genes (L. L., J. Zengel and M. N., unpublished), we conclude that the *in vitro* transcripts from this fragment contain predominantly r-protein messengers. *In vitro* transcripts of λ*spc*1 seem to contain transcripts from the λ genes in addition to the transcripts from the bacterial genes, as can be seen from hybridisation to the separated λ DNA. To test the transcripts from the bacterial DNA, we performed hybridisation experiments using separated λ*fus*2 DNA strands which contain only a small fraction of the λ genome. The results showed that the *in vitro* transcripts for λ*spc*1 hybridised mainly with the λ*fus*2-*l* strand (Table 2, experiment 4). Thus, these results are consistent with the finding that *in vivo* synthesised r-protein mRNA for the genes on λ*spc*1 are transcribed leftwards and

indicate that in general the correct strand is being transcribed under our conditions for *in vitro* transcription.

Multiple transcriptional units

We have shown that insertion mutations, I15 and I16, greatly reduce the expression of many r-protein genes present on the λ*spc*1 genome. A few of the r-protein genes on this phage, however, are apparently not affected to any large extent by these insertions. Among them, the genes for S4, S11, and S13 have been shown to be closely linked to each other and are mapped on the 5% *Eco*RI fragment (Fig. 1 and L. L., J. Zengel and M. N., unpublished). Most of the genes inactivated by the I15 or I16 insertions (genes for the group II proteins in Table 1) have been mapped between the gene cluster for S4, S11 and S13 and the *coli*-λ junction using several deletion mutants of transducing phages (our unpublished experiments). Because the direction of the transcription is from right to left, as demonstrated in our present work, the inactivated genes are distal to the insertion. Although the mechanism of this inactivation of the distal genes by these insertions is not known, the size of the inserted DNA as well as their "polar effect" resemble those of the IS1 and IS2 insertions studied in other systems[4–6]. It is very likely that the r-protein genes affected by the I16 (or I15) insertion belong to a single transcriptional unit, and those not affected (S4, S11 and S13, and others) belong to another one or more transcriptional units. Our present data cannot, however, exclude the possibility that there
Fig. 3 Hybridisation of *in vivo* RNA to separated strands of λ, λ*trkA*, λ*spc*1, and λ*fus*2. Various amounts of RNA prepared from pulse labelled *E. coli* K12 (see below) were hybridised to DNA as indicated. All strands were used in an excess over RNA. Triangles show the average of the bindings to the indicated strands. Binding to individual strands differs slightly, but not enough to be shown on this scale. Preparation of RNA: *E. coli* K12 PR13 (ref. 17) was grown exponentially in glucose–amino acid medium at 37 °C[11]. At approximately 10^8 cells ml^{-1} the culture was labelled with 0.5 μg ³H-uracil (25 Ci mmol^{-1}) ml^{-1} for 4 min. The pulse was terminated by pouring the culture on crushed ice. RNA was prepared from the cells essentially as described before[11]. The RNA preparation had 1.2×10^7 c.p.m. ml^{-1}. Conditions for hybridisation are described in the legend to Table 2.

is a "secondary" promoter between the genes affected and those not affected and that all the r-protein genes carried by λspc1 are cotranscribed in "normal" conditions. The activity of such a secondary promoter could be enhanced by an upstream polar mutation. The present data also cannot exclude the possibility that the genes inactivated by a single insertion belong to more than one transcriptional unit and the inactivation involves a more complicated mechanism. Thus, further studies are required to elucidate the mechanism of the apparent polar effect observed in the present system.

It should also be noted here that while the polar effects resulting from IS1 insertions are very strong in other systems, those resulting from the I15 insertion in our system are only partial. The question whether the IS1 DNA is identical to the DNA inserted in λspc1-I15 must await further experiments.

The genes on λspc1 that code for the group II proteins (Table 1) can function *in vivo* in the presence of the λ repressor (experiments in Table 1 and unpublished data) and so the transcription probably starts from a bacterial promoter, rather than a λ promoter. Such considerations would suggest the presence of a bacterial promoter close to the *coli*-λ junction in λspc1. No experimental proof has been obtained to support this conjecture, however.

Previous experiments using phage Mu-1 suggested that the r-protein genes in the str–spc region are transcribed in the direction of spc to str (ref. 3 and other experiments cited in ref. 1). Our present results demonstrate that the opposite direction is correct. We cannot offer any simple explanation for the results of the Mu insertion experiments. In the previous experiments, the genes inactivated by the Mu phage insertion were not recovered and thus the possibility that these genes were deleted rather than inactivated by a polar effect was not eliminated.

Previous physiological studies on the synthesis of r-proteins in *E. coli* suggested the presence of several transcriptional units for r-protein genes[7]. It is now clear that the organisation of r-protein genes is complex. Many r-protein genes (about 30) are clustered at the str–spc region. Our results strongly suggest that they are organised into at least two transcriptional units. Furthermore, we have previously shown that at least one r-protein gene, the structural gene for S18, is mapped outside

the str–spc region[8,9]. We, and others, have also observed that approximately five other r-protein genes are clustered near *rif* which is far away from the str–spc region (S. R. J., L. L. and M. N., unpublished and J. Friesen, personal communication). Thus, coordinated synthesis of all the r-proteins[10,11] requires a mechanism which coordinates the expression of several r-protein gene transcriptional units.

Simplest statistical geometric model of the simplest version of the multicomponent random packing problem

J. A. Dodds

Laboratoire des Sciences du Génie Chimique, 54000 Nancy, France

A simple, statistical, geometric model of multicomponent random disk packing, which ignores the gaps that occur in real packings, is compared with experimental packings. The model gives a good qualitative description of the changes that occur in packing structures as the proportions of the disks in a mixture changes, and considers the different types of contact that occur between disks. The average coordinance for disk packings is constant for all mixture proportions.

THE sphere packing problem, common to many fields of science and technology, arises in studies of systems involving bubbles, drops, grains, fibres, molecules, and so on[1].

The packing of monosize components is, however, considered

most often and then from the point of view of overall or average properties (such as porosity). That is in spite of the fact that, in practice, mixtures of different sized components are nearly always encountered; in cases such as these the distribution effects (for example pore-size distribution) are very important. In such cases, however, the calculation of the fine structure of the packing is impossible and even measurement is difficult. We therefore present here an alternative approach.

The two-dimensional packing of a mixture of two disk sizes, probably the simplest possible expression of the sphere packing problem, can be considered by using a model designed for multicomponent sphere packing[2,3] but reduced here from three to two dimensions.

The basic hypothesis is that in a random arrangement of disks each disk touches its neighbours. This allows the space to be divided up into triangles formed by lines joining the

centres of contiguous disks (Fig. 1). The hypothesis is, therefore, that gaps, such as those shown by the dotted lines in Fig. 1, do not exist.

This abstraction of the problem allows the effects of size distribution to be considered apart from the less easily defined effects of the perturbation of the structure caused by inevitable,
Fig. 1 Binary disk packing.

irregular gaps. That is, elementary subunits in the packing are calculated but their subsequent assembly to form the packing structure is ignored. The model is limited to the case in which there is interaction between the sizes; effectively to cases in which the diameter ratio is less than 1:6.46. Above that value it is possible to fit a small disk in the space between three large contiguous disks without touching them.

Mathematical statement of the model

In the case of the binary packing of disks of sizes 1 and 2 the space is divided into four types of triangular subunits, each formed by groups of three disks—111, 112, 122, 222. More generally, in an N component disk packing there will be

$$N(N+1)(N+2)/3! \tag{1}$$

different types of triangle. Once the frequency distribution of these different triangles is known, then all of the properties of the idealised packing can be deduced: the porosity, the pore size distribution, the mean coordination number for each disk size, and so on.

Fig. 2 Triangle frequency distribution. Type 111: ×, experimental distribution; a, model distribution. Type 112: ●, experimental distribution; b, model distribution. Type 122: +, experimental distribution; c, model distribution. Type 222: ○, experimental distribution; d, model distribution.
The triangle frequency distribution must be calculated from the relative numbers and sizes of the disks. Two effects come into play: size and number. For example, if there are more disks of diameter 1, then triangles including disks of diameter 1 will be favoured. On the other hand, disks of diameter 2, being bigger, will have more other disks touching them and will form more triangles, therefore, triangles including disks of diameter 2 will be favoured. The probability of a disk taking part in a triangle will be related to Z_i:

$$Z_i = n_i C_i$$

where n_i is the fractional number frequency of disks of size i in the packing, and C_i is the average number of contacts on disks of size i in the packing.

If triangle systems are obtained by random combinations of groups of three disks, then the frequency distribution of triangles in a binary mixture will be given by the respective terms of the expansion of the expression

$$(Z_1+Z_2)^3 \tag{2}$$

or, in a form suitable for programming,

$$(3!/a!\,b!)(Z_1)^a(Z_2)^b \tag{3}$$

where a or $b = 0$, 1, 2 or 3 and $a+b = 3$. That is, the relative frequency of triangles of type 112 is given by

$$(3!/2!\,1!)(Z_1)^2(Z_2)^1 \tag{3}$$

The mean coordinate number for a given disk size is the reciprocal of the mean angle subtended at that type of disk by other disks in the packing, expressed in fractions of a circle. This is not known *a priori* and must be calculated by trial and error. Equations (1)–(3) show that:

$$C_j = (Z_i+Z_j+Z_k+ \ldots)^2/A' \tag{4}$$

where
$$A' = (A_{j(ii)} Z_i{}^2 + A_{j(jj)} Z_j{}^2 + A_{j(kk)} Z_k{}^2 + \ldots)$$
$$+ 2 (A_{j(ij)} Z_i Z_j + A_{j(ik)} Z_i Z_k + A_{j(jk)} Z_j Z_k + \ldots)$$

$A_{i(jk)}$ (Fig. 1) is the angle subtended at the centre of disk i by the lines joining its centre with the centres of two contiguous disks, j and k. For diameter ratios up to the maximum possible considered here (1:6.46), to within about 1%:

$$(A_{j(ii)})^{\frac{1}{2}} \times (A_{j(jj)})^{\frac{1}{2}} \approx A_{j(ji)} \tag{5}$$

This allows equation (4) to be simplified to

$$C_j = \left[\sum_{i=1}^{i=N} Z_i \Big/ \sum_{i=1}^{i=N} K_{ji} Z_i \right]^2 \tag{6}$$

where $K_{ji} = (1/C_{ji})^{\frac{1}{2}}$ and C_{ji} is the number of contacts on a disk type j surrounded completely by disks type i. Equations like (4) or (6) can be solved rapidly and efficiently using the Newton–Raphson technique.

In all calculations made with ternary as well as binary mixtures, with diameter ratios up to the maximum allowed by the model:

$$\sum_{i=1}^{i=N} n_i C_i = \text{constant} \tag{7}$$

For disks, this constant is 6.0.

No formal proof of this has been obtained but the reproducibility of the value 6.0 suggests something more than a

purely fortuitous relationship of the type seen in equation (5). This is perhaps connected with the proven fact that the average Voronoi polygon of any array of points in two dimensions has exactly six sides[4].

Experimental binary disk packings

Experiments have been performed with large disks (20 mm and 40 mm diameter) to be able to distinguish between real contacts and close contacts, based on differences of about 1% of a diameter. Disks were made from steel washers machined to be perfectly circular with a tolerance on the diameter of ± 0.2 mm. To form a two-dimensional packing they were introduced into a

in Fig. 1. The numbers of the different types of 'false' triangle were then counted (Table 1 and Figs 2 and 3).

Figure 2 is the sum of the distributions of the 'true' and the 'false' triangles, as it was found that these two distributions did not differ greatly from each other.

The model

From the results in Figs 2 and 3 and the ratios C_4/C_2 (Table 1), it can be seen that the model gives a good qualitative picture of the variations in packing characteristics with mixture proportions. Table 1 shows also that the total number of contacts on a given number of disks is approximately constant,

Table 1 Model and experimental results

| Disk diameter | % | Number of triangles per experiment | | | Model | | | Coordination numbers | | Experiment | |
		True	False	C	C_4/C_2	Σ_{nc}	C	σ	C_4/C_2	Σ_{nc}
2	90	274	396	5.71			4.39	0.74		
4	10			8.64	1.51	6.00	6.89	0.77	1.39	4.64
2	70	197	188	5.25			4.18	0.64		
4	30			7.74	1.47	6.00	6.49	0.88	1.56	4.87
2	50	148	196	4.91			3.82	0.63

360 by 600 mm Perspex frame one by one in groups of ten, with the required mixture proportions. The packing was not shaken, so as to avoid segregation effects which can be important in mixtures. Each packing was repeated at least twice and represents a counting of around 500 disks, depending on size.
Fig. 3 Types of contact. Type 11: ●, experimental; *a*, model. Type 12: ×, experimental; *b*, model. Type 22: ■, experimental; *c*, model.

Three different mixtures were used. A tracing of the assembly was made and the various countings were made on diazo prints of this tracing. In all cases, disks at the edges to a depth of about two disks were excluded to minimise edge effects.

The centres of contiguous disks were joined and several different counts were made: the numbers of the different types of 'true' triangle; the numbers of contacts on each disk size; the numbers of the different types of contact—that is, between similar disks—1,1 and 2,2—and between dissimilar disks—1,2. The remaining polygons were divided into triangles by joining the closest non-touching disks, as by the dotted lines

as is predicted by the model.

The model describes high density packing with a maximum number of contacts between disks. Not all of these contacts are made, however; it seems that the selection of the contacts not to be made is done randomly and that the gaps do not tend to be associated preferentially with either of the two disk sizes. The influence of the gaps is found only in the absolute values: for example, the total number of contacts per unit sample of disks is 4.72 and not 6. The fact that this reduction is uniform for all mixtures could be used to make the model quantitatively predictive.

It may be concluded that the triangle frequency distribution and the distribution of contact types are not much disturbed by the presence of the gaps. This indicates that, contrary to the influence of the walls, the gaps do not have any ordering influence and that, as the model assumes, the disks touch each other on the basis of random encounters governed only by their relative size and number.

The results also provide some insight to another feature of binary packings, which has been noticed before. Since each type of triangular unit has its own characteristic porosity the variation of the overall porosity with mixture proportions is given by a weighted sum of the four distribution curves in Fig. 2. This provides an explanation for the occurrence of the well known V-shaped, porosity/mixture proportion curves for binary packings. This effect is much more noticeable for sphere packings or disk packings with a wider diameter ratio.

Several points emerge from this study: packings are formed by random encounters between disks; the model predicts the correct distribution of contact types and triangular subunit types; the total number of contacts in a unit sample of disks is constant for all mixture proportions; the gaps in the packing occur in a random fashion.

Discovery of a corona around an early-type star and the problem of mass loss

THE star τ Sco, HD149438, spectral type B0 V, was observed spectroscopically by the Princeton telescope-spectrometer on the Copernicus satellite during June and July 1973. This star is well known[1] as being one of the few early type stars with a small projected rotational velocity, v-sin$i$ = 20 km s^{-1}, thus showing narrow spectral lines with a minimum of overlap or blending. So the spectrum of the star was scanned with a resolution of 0.05 Å over the entire wavelength range from 950 Å to 1,560 Å to obtain a prototype ultraviolet spectrum for an early-B star. This spectrum is in preparation by Rogerson and Upson.

Apart from the numerous spectral features with a full width at half maximum (FWHM) of about 20 km s^{-1} which originate in the photosphere of the star, and the interstellar absorption lines, the spectrum also shows a few very wide absorption lines. These lines are identified as belonging to the spectra of O VI at 1,032 and 1,038 Å, N V at 1,239 and 1,243 Å and Si IV at 1,394 and 1,403 Å. The lines are highly asymmetric with the largest depression close to the laboratory wavelengths and an enhanced short-wavelength wing, which extends to a Doppler velocity of about $-1,000$ km s^{-1}. This suggests that the lines are formed in the expanding outer layers of the atmosphere.

The strong presence of O^{5+} and N^{4+} ions in the outer layers of the star is surprising. From the visual and ultraviolet spectrum the temperature of the stellar photosphere is determined to be about 30,000 K and the stellar atmosphere models predict that the temperature in the layers above the photosphere is less. To produce a significant fraction of the observed highly ionised atoms, the temperature in the outer layers must be[2] of the order of 1×10^5–5×10^5 K. (The production of O^{5+} and N^{4+} by radiative ionisations can be neglected since the required stellar radiation in the far ultraviolet is very strongly absorbed in the photosphere by neutral hydrogen atoms and ionised helium atoms.) Therefore, the temperature in the atmosphere of τ Sco must decrease with height in the photosphere, go through a minimum in higher layers and then increase again to at least a few hundred thousand K.

A similar temperature structure is known in the solar atmosphere, where the minimum is about 4,200 K and from there on the temperature increases outward throughout the chromosphere until it reaches a more or less constant value of about 2×10^6 K in the corona. The large temperature is due to the dissipation of mechanical energy in the form of acoustic waves in the lower chromosphere and possibly by Alfven waves in the corona[3]. The mechanical energy in the Sun is supposed to originate in the unstable hydrogen convection zone below the photosphere.

Main sequence stars with effective temperatures greater than about 8,300 K are not expected to have well developed hydrogen convection zones nor to generate a large mechanical energy flux which could produce a stellar corona[4].

A possible mechanism for generating a mechanical energy flux in hot stars has been proposed by Hearn[5,6]. He has pointed out that in the presence of a strong radiation field,

such as in early type stars, density waves can grow and propagate outwards due to the absorption of radiation. This theory predicts a mechanical energy flux of the order of 10^7 erg cm^{-2} s^{-1} for a main sequence B0 star, which in analogy to the solar chromosphere, seems to be sufficient to heat the outer layers to a few hundred thousand K.

The presence of a high temperature region (called a corona, in analogy to the solar case) around early type stars may provide the clue to the understanding of mass loss from hot stars. The observed expansion velocities are generally accepted to be caused by radiation pressure acting primarily on the resonance lines of abundant ions[7]. An important limitation to the efficiency of this mechanism is the fact that the line transitions which are most suitable for absorbing momentum from the radiative flux in the outer atmospheric layers are also extremely effective in the photospheric layers in the reduction of the needed flux. This problem can be illustrated by the very small rates of mass loss predicted by Lucy and Solomon for stars with effective temperatures slightly greater than 30,000 K, at type B0, where the photospheric C IV lines are very strong.

This difficulty is overcome if the outer atmosphere is hotter than the photosphere, because the abundant ions in the outer atmosphere are different from the photospheric constituents. The presence of O VI ions in the corona, having resonance lines at wavelengths near the stellar flux maximum, is especially important in this respect. If 10% of the coronal oxygen atoms are in the form of O^{5+} and the oxygen abundance is the same as in the Sun, the outward directed radiative force exerted on the gas due to the O VI lines exceeds the inward directed gravitational attraction by a factor of four in τ Sco. A preliminary estimate indicates a rate of mass loss of about $10^{-8} M_\odot$ yr^{-1}. This is about two orders of magnitude less than the mass loss rate from the Orion OB supergiants[8].

How unique is τ Sco? In its visible spectrum there is no indication that the star is different from other B0 V stars, except for its small projected rotational velocity. If the star is normal, as we expect, other early-B stars may be surrounded by coronae as well. A preliminary check of the Copernicus files has indicated that traces of O VI lines are detectable on the lower resolution spectra of several other early type stars. Further details will be published elsewhere.

North–south component of the interplanetary magnetic field and large scale auroral dynamics

THE role of the north–south component B_z of the interplanetary magnetic field on magnetospheric processes, in particular on magnetospheric substorm processes, has caused some controversy[1-3]. It has been generally thought that the southward turning of the B_z component leads directly to a series of growth phase processes which trigger the expansive phase of substorms. On the other hand, auroral observations made along the meridian chain of stations in Alaska showed that substorms occur frequently along a contracted auroral oval (namely, beyond the poleward field of view at auroral zone stations) even when the B_z component is directed northward $(B_z > 0)$[4].

Fortunately, both large scale auroral photographs taken from the DMSP satellite (October and December 1972, and January 1973), and the interplanetary magnetic field data during the corresponding periods (from the HEOS satellite) have recently become available. The results are ideal for

frequency of substorms for contracted ovals[5]. Thus, on the basis of the ISIS-2 and DMSP–HEOS satellite data, one can conclude that the occurrence of substorms does not depend on the size of the oval, except when the oval becomes minimum (that is, during prolonged periods of a large positive B_z component).

I now examine theoretical implications of this finding. Let φ_D be the production rate of merged (or open) field lines along the dayside X line. This quantity is also believed to be equal to the potential drop along the X line and also to the potential drop across the dawn–dusk meridian in the polar cap[6,7]. φ_N is the production rate of reconnected (or closed) field lines along the nightside X line.

Consider the quantity defined by

$$S = \int_0^\tau (\varphi_D - \varphi_N)\,dt$$

where the time $t = 0$ is chosen at the time when the interplanetary magnetic field begins to decrease after having a large northward component for an extended period. Note that the quantity S defined here is equal to $(A_1 - A_0)B_p$, where A_0 and A_1 denote the area of the minimum size oval and of an expanded oval, and B_p denotes the magnetic field intensity
Fig. 1 Hypothetical change of the B_z component and the resulting changes of φ_D, φ_N, $\varphi_D - \varphi_N$ and

$$S = \int_0^\tau (\varphi_D - \varphi_N)\,dt.$$

settling the controversy; it seems that the occurrence of substorms does not depend on the size of the auroral oval, except for periods when the oval contracts to its minimum size (midnight latitude $\simeq 72°$).

Full details of this study will be reported in detail elsewhere. In brief, the occurrence of auroral substorms depends on neither the sign of the B_z component, nor the sign of the dB_z/dt, except for prolonged periods ($\gtrsim 6$ h) of the large ($\gtrsim 5\gamma$), steady, positive (northward) B_z field. During these exceptional periods, the midnight portion of the oval contracts to invariant latitude of about $72° \sim 73°$ (the highest latitude observed so far for a quiet oval). Thus, this contracted oval can be called the minimum size oval. No substorm features are observed along the minimum size oval; the corresponding state of the magnetosphere may be considered to be the 'ground state'.

What magnetospheric quantities can one infer, on the basis of these findings, as a controlling factor of the occurrence of substorms? Photographs taken from ISIS-2 have already indicated that there is no drastic decrease of the occurrence

in the polar ionosphere. Thus, we may write

$$S = \int_0^\tau (\varphi_D - \varphi_N)\,dt = B_p(A_1 - A_0)$$

Figure 1 illustrates schematically time variations of φ_D, φ_N, $(\varphi_D - \varphi_N)$ and S when the north–south component of the interplanetary magnetic field B_z varies from a large positive value to a negative value for about two hours and then back to a large positive value again. Note that an extended period of a large positive B_z value is the initial condition.

The immediate response of φ_D to the B_z change has been observed[6]; the motion of the cusp or of the mid-day aurora towards the Equator closely follows B_z changes. But it is not yet known accurately how rapidly the midnight portion of the oval responds to the initial B_z change. This depends on how quickly the information on a change of φ_D can reach the nightside X line and the production rate φ_N begins to

respond to it. The minimum delay time τ_m can be roughly estimated by

$$\tau_m = B_p(A_1 - A_0)/\varphi_D \simeq 40 \text{ min}$$

where

$$\varphi_D = (400 \text{ km s}^{-1}) \times (5\gamma) \times (15 R_E)$$

and A_0 and A_1 are assumed to be bounded by the latitude circles of 72° and 65°, respectively.

Because of this delay, the quantity $(\varphi_D - \varphi_N)$ should increase initially. This quantity is directly proportional to the rate of change of the polar cap area, namely the area bounded by the auroral oval. When $(\varphi_D - \varphi_N)$ is positive, the oval expands. But φ_N begins to increase about 40 min to 1 h after $t = 0$, and eventually a new steady state $\varphi_D = \varphi_N$ will be reached. Then the auroral oval ceases to expand.

Suppose the B_z then begins to increase after maintaining a large negative value for about two hours. The quantity φ_D responds immediately to the B_z change and begins to decrease. But the corresponding φ_N variation will again be delayed for about 40 min to 1 h, until the new information on B_z can reach the nightside X line. During this period, the quantity $(\varphi_D - \varphi_N)$ becomes negative, and thus the oval contracts. If a large B_z value is maintained for a prolonged period, both φ_D and φ_N reach the same minimum value.

Meanwhile, the quantity S increases until $(\varphi_D - \varphi_N)$ becomes zero, and then begins to decrease. Eventually, S will become zero after a prolonged period of a large B_z value (that is, when both φ_D and φ_N reach the same minimum value).

In constructing Fig. 1, I assumed that both φ_D and φ_N have a finite value even when the B_z component has a large positive value. This is because the magnetotail (a product of the solar wind–magnetosphere dynamo) seems to be a permanent feature. At the lunar distance $(60 R_E)$, there is no significant difference in the structure of the magnetotail for both low K_p values $(K_p \leqslant 1+)$ and high K_p values $(K_p \geqslant 2-)$[10]. Thus, there must always be a finite amount of open flux $(= B_p A_0)$,
Fig. 2 DMSP photograph (in negative) taken at 2057 UT on December 24, 1972, together with an approximate geographic area covered by the photograph; it shows also the invariant latitude lines at 100 km altitude (thick lines) and geographic latitude lines (thin lines).

Fig. 3 DMSP photograph (in positive) taken at 1252 UT on January 12, 1973; see the caption for Fig. 2.

even when B_z has a large positive value for an extended period. During such a period, the auroral oval has the minimum area A_0.

So the magnetospheric substorm can be considered as a process by which the magnetosphere tends to remove the excess energy ε_s associated with S. When the auroral oval at a particular time is significantly greater than its minimum size,

$$\varepsilon_s \simeq (L/R_T^2 V_i \pi^4) S^2$$

where L is the length of the magnetotail, R_T is the radius of the magnetotail and V_i is the speed of the solar wind.

Figure 2 shows one of the smallest auroral ovals observed by the DMSP satellite. It was taken during a prolonged period of a large positive B_z value. Figure 3 shows an intense auroral substorm along an expanded medium size oval; this event occurred when the B_z component was negative. There is a considerable difference in the size of the oval and auroral activity, as expected from the above equation.

Natural halocarbons in the air and in the sea

ORGANOCHLORINE compounds are usually taken to be man made; yet methyl chloride has been demonstrated as a product of microbial fermentation[1] and of the smouldering combustion of vegetation (A. E. O'Keeffe, personal communication) and Zafiriou[2] has predicted its ubiquitous presence in the environment. Here I report measurements of methyl chloride and other halomethanes in the air and coastal waters of southern England between December 1974 and April 1975. These measurements confirm those of R. A. Rasmussen (personal communication) who found methyl chloride in rural air over the West Coast of the USA; they reveal methyl chloride as the dominant halocarbon of the atmosphere. The possible bearing of this discovery on the chlorine-catalysed destruction of stratospheric ozone is discussed.

Analysis was by gas chromatography using an electron capture detector which was operated at a temperature of 270 °C. This high temperature encouraged the otherwise sluggish reaction of methyl chloride with free electrons[3]. 5-ml air samples were analysed directly and water samples were analysed by taking 5-ml samples of nitrogen previously equilibrated with the water. The limit of detection for methyl chloride was 8.5×10^{-11} by volume.

Figure 1 compares the ambient concentration of methyl chloride and CCl_3F at Bowerchalke, southern England from
Fig. 1 Aerial concentration of CH_3Cl (+) and of CCl_3F (solid line) in parts per 10^9 and 10^{12} by volume respectively.

December 1974 until April 1975. The concentration of both gases varied with wind heading but methyl chloride was most abundant with air from the Atlantic whereas CCl_3F was most abundant with air from continental Europe. The mean concentration of methyl chloride over this period was 1.14×10^{-9} by volume. Table 1 lists the concentrations of halocarbons in seawater collected on the Kimmeridge ledges 30 miles south of the air sampling site. These inshore waters, rich in kelp, can be seen to carry large but variable amounts of halocarbons. Table 2 lists observations of methyl iodide in seawater during the voyages of the RV Shackelton in 1971 and 1972 and the RV Meteor in 1973. The first voyage covered the Northern and Southern Atlantic and Antarctic Oceans, the second the North Atlantic and the Caribbean Oceans. The table also includes some measurements of seawater concentrations of methyl iodide over kelp beds in

South-west Ireland. These latter measurements were during the summers of 1973 and 1974.

Methyl iodide has been found in all ocean waters so far examined and may be a common product of marine algae. The large kelp, particularly *Laminaria*, seem to specialise in the production of methyl iodide and water in the vicinity of the *Laminaria digitata* beds of South-west Ireland was found to contain one thousand times as much as is found in the open oceans. Other inshore algal beds, for example those of *Fucus*, showed no such increase. If methyl chloride is the product of the reaction between methyl iodide and the chloride ion of seawater[2], then the distribution of methyl chloride and perhaps also methyl bromide might be expected to follow a similar pattern to that of methyl iodide. So far only inshore waters have been examined for these compounds, where the concentration is so much greater than that which would be in equilibrium with the air that the sea is undoubtedly a strong source. If the halomethanes are the halogen gases discovered in the pioneering measurements of Duce and his colleagues[4,5] then the methyl halides are indeed ubiquitous.

The rate of reaction of methyl chloride with OH in the troposphere is such[6] that if this were the sole sink the residence time would be 0.37 yr. Applying this value to the observed mean concentration of 1.14×10^{-9} suggests a source strength of 28 Mt yr^{-1}. The industrial production of methyl chloride in 1973 was 0.35 Mt; this was used almost entirely as a chemical intermediate in the production of other compounds and did not reach the atmosphere as such. The atmospheric CH_3Cl is therefore almost certainly not a direct industrial emission. From the model introduced by Liss and Slater[7] some estimates of the seawater concentration neded to sustain a flux of 28 Mt yr^{-1} to the atmosphere can be calculated. This would suggest that with an aerial concentration of 1.14×10^{-9} the mean seawater concentration would need to be 1.9×10^{-8} ml of gas per ml of seawater. This requirement was reached on one occasion for the waters examined but an extended survey will be needed to determine the proportion of methyl chloride of marine origin. Approximately 1% of the chlorine content of vegetable matter is converted to methyl chloride during smouldering combustion. Grass and forest fires, stubble burning, and slash and burn agriculture are therefore potential sources also.

What is the significance of the high concentrations of methyl chloride for the present concern over the chlorine-catalysed destruction of stratospheric ozone? Unlike the freons, methyl chloride is comparatively unstable chemi-

cally and the greater part of it would be destroyed in the troposphere. But methyl chloride has a source which is globally distributed and a residence time long enough to permit mixing in the troposphere. In these circumstances the observed ground level concentrations are likely to be representative and extend to the tropical tropopause. The proportion of chlorine conveyed to the stratosphere as methyl chloride to that conveyed as freon molecules will therefore be as their concentrations at the tropical tropopause. If other chlorine compounds are included, the present estimates suggest that less than 20% of the chlorine entering the stratosphere is in the form of freon[6]. Newell[8] calculates that the residence time for a molecule in the stratosphere between the 10 and 100 mbar levels is 2 yr. During this time nearly all of the methyl chloride entering the stratosphere will have been destroyed, releasing its chlorine. Because of their much greater stability the most likely fate of freon molecules entering the stratosphere is to return back to the troposphere. When this additional factor is taken into account the present production of chlorine in the stratosphere is mostly from naturally occurring methyl chloride. If the freons are allowed to accumulate in the atmosphere without hindrance eventually their concentration may reach levels which are hazardous. But at present they seem to constitute only a minor stratospheric chlorine source.

It is reasonable to assume that any man-made perturbation of a major compartment of the atmosphere such as the stratosphere is at the very least undesirable. In this debate, however, it is always assumed that ozone depletion alone is the serious problem and potential threat; the possible dangers of ozone accretion are in this context considered as irrelevant. An alternative view of the significance of odd nitrogen and odd chlorine in the atmosphere comes from considering the possibility that the cycling of gases by the biosphere is not merely passive but represents an active process concerned with homeostasis[9]. In the context of this hypothesis the large scale biosynthesis of methyl chloride and nitrous oxide, and the lesser production of the more potent methyl bromide, suggests a natural process for ozone depletion. Could it be that the biosynthesis of these compounds responds to some function of stratospheric ozone density and acts as a regulator?

I thank Drs S. A. Penkett and D. Johnson for the identification of methyl chloride, and Shell Research Ltd for support.

Terrain units in eastern Antarctica

APPROXIMATELY 12,000,000 km[2] of bedrock in Antarctica is inaccessible, except to remote sensing, beneath an ice sheet up to 4.5 km thick. The topographical and geological pattern of the subglacial continent has, consequently, been little investigated and no more than a few geophysical measurements have been obtained. The availability of continuous records of bedrock topography from airborne radio echo sounding, however, now

facilitates the calculation of statistics of terrain roughness, which can be used quantitatively to differentiate subglacial regions, to cluster similar units, and to indicate associations or characteristics related to geological factors[1].

A joint programme between the Scott Polar Research Institute (SPRI) and the US National Science Foundation (NSF) has obtained over 300,000 km of profiles in Antarctica since 1967 using pulse-modulated radar operating in the frequency range 35–60 MHz (refs 2–6). Some of these results have been used to define and interpret terrain units in eastern Antarctica.

Information on terrain roughness is available at two scales. A qualitative examination of detailed bedrock relief maps (contour interval 250 m) compiled following radio echo exploration (SPRI Antarctica Radio Echo Sounding Map Series A, sheet 3, 1974; scale 1 : 5,000,000) allows the delimitation of major physiographic provinces[7] (Fig. 1). Quantitative measures of the fine structure of surface roughness can be obtained from statistical analysis of the variation of relief within macroscale regions.

Vertical and horizontal variations in bedrock elevations have been calculated by the use of two simple statistics—the dispersion of elevations about the mean normalised to zero (D, standard deviation) and the autocorrelation distance (R_{xd}) calculated from the normalised autocorrelation function (with zero mean):

$$R_x = (n/n-k) \left[\left(\sum_{x=1}^{n-k} V_x \times V_{x+k} \right) \bigg/ \sum_{x=1}^{n} V_x^2 \right]$$

where V_x = discrete bedrock elevation; n = total number of elevations; k = lag of unit 1.5 km (the sample interval).

R_{xd} is defined as the lag to the jth % confidence level, usually taken as 95%. It is a distance over which roughness shows little or no statistical variation within given limits.

D and R_{xd} were computed for radio echo profile elevation data within macroscale regions of eastern Antarctica (Fig. 2). Two topographic groups can be identified, one comprising lowland areas with D values < 180 m (the Wilkes Basin and the basin in central eastern Antarctica) and a second, less homogeneous group of highland regions with values of $D \geqslant 200$ m (the Gamburtsev Mountains, subglacial portions of the Transantarctic Mountains and the massif in central eastern Antarctica).

The Gamburtsev Mountains fall into two distinct parts: one

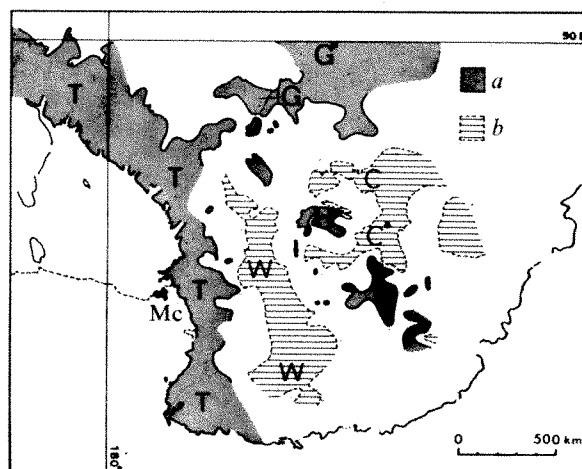
Fig. 1 Major large-scale terrain regions of eastern Antarctica. T, Transantarctic Mountains; G and G*, Gamburtsev Mountains; H, highland massifs within central eastern Antarctica; W, Wilkes Basin; C and C*, central basin of eastern Antarctica; Mc, McMurdo Sound; *a*, terrain over 250 m; *b*, terrain below 500 m. (Both relate to present sea level.)


Fig. 2   Average terrain roughness characteristics of topographic units of eastern Antarctica. Bars indicate root mean squares of measurements. G and G*, Gamburtsev Mountains; H, central massif in eastern Antarctica; T, Transantarctic Mountains; W, central portion of Wilkes Basin; W*, marginal zones of Wilkes Basin; C*, northerly portion of central eastern Antarctic Basin; C, southerly portion of central eastern Antarctic Basin.

has a very high R_{xd} value indicating a smoother, more regular topographic surface, but is dissected by deep valleys to yield a commensurately high D value; the other, with a low autocorrelation distance, is typical of very rugged, rough mountainous terrain: values for D and R_{xd} are comparable with similar statistics obtained from other high latitude 'alpine' areas (for example, Alaskan ranges)[1].

Such contrasts within contiguous mountain zones probably originate from differences in the geological pattern. Unfortunately, no supporting geophysical information is available for this region. Nevertheless, it has been suggested that the Gamburtsev Mountains may have formed part of a large geosynclinal series deformed during a late Proterozoic–early Phanerozoic orogeny; an early Proterozoic deformational event has also been proposed[1]. The presence, however, of at least two distinct terrain provinces suggests a more complicated history of block formation and uplift. It may be that periods of epeirogenic reactivation in the Gamburtsev Mountains did not have uniform effects, either in time or place, leading to later diversification of terrain. The same result could also be the product of the differential stripping of an epiplatform cover developed during the Phanerozoic.

The Transantarctic Mountains and massifs within central eastern Antarctica show statistical similarities, but both are quite different from the Gamburtsev Mountains. The structural control of relief in both the exposed and the subglacial parts of the Transantarctic Mountains is partially attributable to the presence of the sub-horizontal sediments of the Beacon Supergroup and associated intrusive bodies[1,9,10]. Values of terrain roughness indicate that the central massif also falls within the same province of Phanerozoic sedimentation. Smaller R_{xd} values for the subglacial Transantarctic Mountains may be attributable to the more active erosional development of the mountains in the mid-Cainozoic, during the growth phase of the eastern Antarctic ice sheet[11], and to the later fluctuations of its margin in that zone[12].

The two major basinal areas of eastern Antarctica show strong similarities in terrain roughness, yet although they possess low D values they cannot be termed plain-like since they exhibit equally low R_{xd} characteristics.

The Wilkes Basin *sensu stricto* and its marginal areas were analysed separately. Results suggest that this depression (below present sea level), with only small scale surface irregularities along its axial core, is rimmed by a much rougher transition zone. Such

differentiation implies that the basin may contain a smoothing cover of Mesozoic and Cainozoic deposits which is absent from its flanks because of erosion. Calculations from isolated magnetic measurements over part of the Wilkes Basin provide limited evidence for the presence of a discontinuous, sedimentary sequence up to 6 km thick in places[13].

Similar, but slightly less marked, differences exist between two portions of the central eastern Antarctic basin. Since the margins of this basin show no distinctive roughness characteristics compared with the Wilkes Basin, any differences may result from a slightly greater surface dissection of a sedimentary mantle in the northern sector of the basin though it cannot be positively stated that sediments line the depression because of the absence of geophysical observations. In a small isolated basin beneath the Soviet Vostok base, 300 km to the south, however, seismic investigations of the upper crust indicate a thin layer of sediments[14].

These analyses may be important aids to the geological interpretation of inland areas of Antarctica and could be used as a primary reconnaissance tool for the location of critical areas worthy of detailed study using other geophysical techniques.

Mechanochemical availability

THE thermodynamic functions 'availability' and 'maximum work', as they are usually defined[1-3], are generally inapplicable to systems that interest the biologist and electrochemist for the reasons shown below. Here I propose the redefinition and generalisation of both functions, and explicitly define a thermodynamic property, the 'mechanochemical availability', that provides a measure of the maximum usable mechanochemical work that can be released in the interaction of a contractile system with a source or sink of chemical potential of constant intensive state.

The 'maximum work' function

$$\Delta W \equiv \Delta U - T_r \Delta S \qquad (1)$$

is the work input along the singular process path that takes a system adiabatically and reversibly (isentropically) from its initial temperature, T_{system}, to the temperature of an interacting isothermal reservoir, T_r, (process 1–c) and that has all
Fig. 1 T_1 may be greater than or less than T_r, but in this figure $T_1 < T_r$.

heat exchanges occurring subsequently and reversibly at T_r (process c–r) (Fig. 1a and b).

Thus

$$W_{1cr} = \Delta U_{1r} - Q_{1cr} = \Delta U - T_r \Delta S \equiv \Delta W \qquad (2)$$

The 'availability' is defined as

$$\Delta B \equiv \Delta W + P_r \Delta V \equiv \Delta U + P_r \Delta V - T_r \Delta S . \qquad (3)$$

When a system is capable of exchanging several work modes with its environment, equations (1) and (3) are of limited use or interest. To illustrate this deficiency, consider that an open mechanochemical system can engage in the following reversible work modes

$$W = \sum_i W_i = -\int_1^r P dV + \int_1^r f dL + \int_1^r \sum_i \mu_i dn_i \qquad (4)$$

which in turn equals

$$\Delta U - T_r \Delta S \equiv \Delta W \qquad (5)$$

when the system is constrained so as to transfer heat reversibly at T_r.

If the system is further constrained to operate at constant P_r, then

$$\Delta W = -P_r \Delta V + \int_1^r f dL + \int_1^r \sum_i \mu_i dn_i \qquad (6)$$

and

$$\Delta B = \int_1^r f dL + \int_1^r \sum_i \mu_i dn_i \qquad (7)$$

Equations (6) and (7) are deficient because they fail to separate the contraction work, $\int f dL$, from the chemical potential interchange, $\int \Sigma \mu dn$. Only the former term measures the useful mechanical work exchanged with the environment, yet the magnitude of this term is completely obscured in equations (6) and (7). In a mechanochemical system the 'availability of contraction work' is the significant or relevant quantity.

This deficiency may be removed by defining ΔW more generally:

"ΔW is the work input along that combination of reversible process paths which brings a system from its initial equilibrium state to a final state in equilibrium with an interacting reservoir of fixed state, said paths being such that all heat transfer occurs

at T_r and all matter transfer occurs at the potential of the reservoir (μ_{ri} or V_r)."

It now follows that the work input to a system so constrained is

$$W = \Delta U - Q = \Delta U - T_r \Delta S$$
$$= -\int_1^r P dV + \int_1^r f dL + \sum_i \mu_{ri} \Delta n_i \qquad (8)$$

As a further consequence, the 'maximum mechanochemical work' can now be defined as

$$\int_1^r f dL \equiv \Delta W_{mc} = \Delta U - T_r \Delta S + P_r \Delta V - \sum_i \mu_{ri} \Delta n_i \qquad (9)$$

if the system operates at P_r, and the 'mechanochemical availability' may now be defined as

$$\Delta B_{mc} \equiv \Delta W_{mc} - f_r \Delta L = \int_1^r f dL - f_r \Delta L \qquad (10)$$

or

$$\Delta B_{mc} \equiv \Delta U - T_r \Delta S + P_r \Delta V - \sum_i \mu_{ri} \Delta n_i - f_r \Delta L \qquad (11)$$

The significance of equations (9)–(11) is illustrated by Figs 2 and 3 which show the computation paths for ΔW_{mc} and
Fig. 2 Area $a = \Delta B_{mc}$; area $b = -f_r \Delta L$.

ΔB_{mc}, where 1 is any initial state of the system and r is the state of the system when in equilibrium with an interacting reservoir at T_r, P_r, μ_{ri} and f_r. Process 1–c is an isomolar reversible process which reduces the chemical potential of the system reversibly from μ_1 to μ_r. Process (c–r) then allows mass transfer at constant μ_r.

As can be seen from equations (10) or (11) the area (1–c–r–d–1) is equal to the mechanochemical availability.

At constant T_r and P_r, the cyclic integral of the Gibbs equation for a mechanochemical system:

$$\oint dU = T_r \oint dS - P_r \oint dV + \oint f dL + \oint \sum_i \mu_i dn_i \qquad (12)$$

reduces to

$$\oint f dL = -\oint \sum_i \mu_i dn_i \qquad (13)$$

from which it follows that area (1–c–r–d–1) in Fig. 2 equals

the negative of area (1–c–r–d–1) in Fig. 3, if only one component is exchanged with the reservoir, and

$$\sum_i [\text{areas } (1\text{--c--r--d--1})_i]$$

if i components are exchanged.

An analogous representation of the ΔB of equation (3), that is, the availability in a thermally activated expansion work system, is shown by the cycles (1–c–r–d–1) in Figs 1 and 2. The ΔB cycles always involve the properties of the work coupling and potential terms that appear in the Maxwell relations for the system. For a thermally activated expansion work system the relevant Maxwell relations in Jacobian form[4] are

$$[P, V] = [T, S] \tag{14}$$

whereas for a mechanochemical system at constant T and P they are

$$[f, L, T, P] = -[\mu_i, n_i, T, P] \tag{15}$$

The graphical representation of ΔB always consists of a cycle in which a constant n_i (or S) process is followed by a constant μ_i (or T) process, with the cycle completed by constant P and constant V processes or constant f and constant L processes. The area of the cycle is always less than or equal to zero.

By analogy the electrochemical availability may be defined as

$$\Delta B_{ec} \equiv \Delta U - T_r \Delta S + P_r \Delta V - \sum_i \mu_{ri} \Delta n_i - V_r \Delta_q \tag{16}$$

where V and q are voltage and charge, and a 'general availability function' may be defined as

$$\Delta B_g \equiv \Delta U - T_r \Delta S + P_r \Delta V - \sum_i \mu_{ri} \Delta n_i - f_r \Delta L + \sum_i F_{ri} \Delta X_i \tag{17}$$

where $\Sigma_i F_{ri} \Delta X_i$ represents the sum of all other reversible work forms expended against the interacting reservoir.

Is path (1–c–r) the maximum work path?

Curve (1–k–r) in Fig. 4 represents an arbitrary reversible mechanochemical process connecting the initial state (1) to the reservoir state (r). The area under (1–k–r) is clearly greater than area under the ΔW path (1–c–r).

Path (1–a–b–r), consisting of isomolar processes (1–a) and (b–r) and isopotential process (a–b), is so drawn that the area under (1–a–b–r) is equal to that under (1–k–r) (Clausius' theorem[5]).

For a constant temperature–constant pressure reversible
Fig. 4

Fig. 3
mechanochemical process whereby a system at 1 interacts reversibly with a reservoir at r

$$\int_1^r dU = T_r \int_1^r dS - P_r \int_1^r dV + \int_1^r f dL + \int_1^r \sum_i \mu_i dn_i \tag{18}$$

or

$$\int_1^r f dL = \Delta U_{1r} - T_r \Delta S_{1r} + P_r \Delta V_{1r} - \int_1^r \sum_i \mu_i dn_i \tag{19}$$

It follows from equation (19) that if the $\int \mu_i dn_i$ along path (1–k–r) is equal to the integral along (1–a–b–r), then the contraction works

$$\int_1^r f dL$$

for both paths are also equal. Now the work of process (1–a–b–r) exceeds that of process (1–c–r) by

$$\sum_i \left[\text{area } (a\text{--b--r--c--a})_i \right]$$

For process (1–a–b–r) to occur reversibly, however, it must absorb chemical work ($\mu_i dn_i$) at μ_b which is greater than the μ_r of the environment. A Carnot chemical pump[6] (the chemical work analogue of a heat pump) will therefore be needed to transfer this chemical work from the μ_r to the μ_b reversibly. The work input to this pump(s) is exactly equal to

$$\sum_i \left[\text{area } (a\text{--b--r--c--a})_i \right]$$

so that the net reversible work obtainable from the system (1) interacting with reservoir (r) is (−) the area under (1–c–r) plus ($\Delta U - T_r \Delta S + P_r \Delta V$), or $\int f dL$ along path (1–c–r).

Note added in proof: I thank Professor J. Keenan for pointing out that equation (9) is analogous to equation (55) of ref. 7.

Wet preparation of 'water glass' from the hull ash of Egyptian rice

THE FAO and other organisations have suggested useful applications for the rice hull in agriculture[1]. But promotion of the use of the material for industrial applications was ignored. The use of the hull and its ash in the preparation of furfural and ceramic products has now been shown to be possible[1], but only the preparation of furfural from the hull has been established (in the USA and Italy) as a sound industrial process. Nevertheless, the furfural industry consumes only a small fraction of the material available, and research into other potential applications is obviously desirable. The work described here is an attempt at the wet preparation of water glass by decomposing the hull ash with sodium hydroxide solution at a moderately high temperature.

Water glass is normally prepared by fusing the appropriate quantities of sodium carbonate and sand at a temperature around 1,400 °C to produce a soda–silica glass This is converted into a viscous liquid through the action of water vapour under pressure[2]. The material has many applications in detergents, adhesives, ceramics, paper, textiles and other industries.

The annual world production of rice is $\sim 250 \times 10^6$ t, of which about 10^6 t are produced in Egypt. The hull constitutes about 20% of the rice grains. The material has a very low bulk density (about 0.13 g cm^{-3}), and thus occupies

a very large space. It also has a high silica content which makes it of little value as food for animals. The hull is used as a fuel, especially in some rice mills. When well burnt it leaves a whitish fluffy voluminous ash which retains the original shape of the hull, and consists chiefly of silica in an amorphous form[1].

For the determination of the ash content of the hull and the thermal behaviour during ignition, thermogravimetric (TG), differential TG and differential thermal analysis (DTA) graphs were established on a Model OD-102 Hungarian-made Derivatograph.

Figure 1 illustrates TG, DTG and DTA curves for a 340-mg sample of the hull. The sample was heated from room temperature to 1,020 °C in an atmosphere of air at a heating rate of 10 °C min^{-1}, using alumina as the inert reference. The DTA curve shows an initial endothermic peak at about 130 °C corresponding to the loss of adsorbed water. This is accompanied by a similar endothermic DTG peak at a slightly lower temperature (115 °C), and a loss in weight (represented by the TG curve) of about 4.4% of the initial sample weight. The thermal decomposition of the hull is characterised by two exothermic DTA peaks at about 350–400 °C and a composite endothermic DTG peak with the principal apex at 330 °C. These peaks are probably characteristic of cellulose and hemicellulose which are the major constituents of the organic part of the hull. Corresponding to these reactions there was an abrupt loss in weight of about 36.6% of the initial sample weight. The decomposition of the remaining part of the hull was gradual and was completed at about 942 °C after which the weight of the residual ash became fixed at 60 mg (about 18% of the original sample weight).

Complete chemical analysis of the ash remaining after the complete burning of the rice hull was carried out by the method described by Riley[3]. Table 1 presents the percentages of its various constituents, the main one being silica (91.28%). On washing the ash with 0.5 N HCl overnight the silica content rose from 91.28% to about 95.5%. This is chiefly because of the preferential leaching of alkalis and other basic constituents in the form of chlorides.

The decomposition of the ash was carried out in a bomb of 250 ml capacity, made of stainless steel and placed in a thermostatically controlled kiln. In each experiment 5 ml of distilled water was mixed with 5.0 g of a mixture of ash and sodium hydroxide, which had a silica–soda ratio of 2 : 1. The bomb containing the mixture was then placed in the kiln, which was previously adjusted to the required temperature, for the required time. After the experiment was completed, the bomb was taken out of the kiln, cooled to room temperature and opened The contents were then discharged in a 250-ml beaker, using 30–40 ml water and quickly filtered through sintered glass For determining the degree of decomposition of the ash, the filtrate was analysed for its silica content. Figure 2 illustrates the time dependence of decomposition at 100, 125, 150, 175 and 225 °C. The fraction decomposed increases with time and temperature, the reaction being fast in its early stages and slower as complete decomposition

Fig. 1 Ash content of the hull of Egyptian rice.
Fig. 2 Time dependence of decomposition of the raw ash at different temperatures.

is approached. Nearly complete decomposition is achieved after 5, 4, 2, 1 and less than 0.5 h at temperatures of 100, 125, 150, 175 and 225 °C, respectively.

For comparison raw ash, acid washed ash and finely powdered quartz and fused silica (−150 mesh) were subjected to a decomposition experiment at 150 °C for 1 h. The results are given in Table 2. The raw ash is much more easily decomposed than the other forms of silica. The acid treated ash is even more easily decomposed. This can be attributed to the partial leaching of cations such as Al^{3+}, Ca^{2+} and Mg^{2+}, which are known to suppress the dissolution of silica in alkali solutions by precipitating it as silicates[4].

The explanation of the decomposition of the ash by NaOH, can be simplified by taking the relatively simple structure of pure silica as a first approximate model for the more complicated structure of the ash. The effect of other cations can be treated separately.

In all forms of silica, silicon is known to be tetrahedrally coordinated to four oxygen atoms. Within the material, the coordination of oxygen and silicon of the tetrahedral units is satisfied. At the bounding surface, however, silica may expose incomplete tetrahedra and the surface ions will strive to complete their coordination. In contact with aqueous solutions the exposed ions will add hydrogen or hydroxyl ions so that the surface is ultimately covered with Si–OH groups. The hydrogen of the Si–OH group is ionisable and may, in favourable conditions, leave the silica surface in a negatively charged state. According to the details of the structure, there are four ways in which these Si–OH groups may be exposed at the surface[5,6] (Fig 3). These four types show enormous variations in resisting attack by aqueous solutions. Although type I is very unstable in the presence of water, type IV is completely unreactive to alkalis[5]. A demonstration of the importance of the surface structure is provided by low quartz. The basal plane shows a rate of attack by aqueous solu-

tions a hundredfold greater than the prism faces. The former is known to present type II exposure whereas the latter alternates between type II and type III, chiefly existing in the more resistant type III (refs 5 and 6). Noncrystalline silicates such as glasses and rice hull ash would be expected to present surfaces in which the four structural types exist.

In the rice hull, cellulose, hemicellulose and other carbonaceous material, which interlink the structural silicate units, are converted into CO_2 and H_2O by burning. As these materials constitute some 80% of the hull, the ash would be expected to be left in a state of polymerisation from which it can be more easily decomposed than pure forms of silica. This is, indeed, the case (Table 2).

In fact, simple shaking of ash with water at room temperature for a few minutes, brought about the maximum solubility of silica in water (about 0.01%). This supports the view that the structural units in the ash contain a high proportion of the easily soluble monomeric and dimeric units of silica.

The presence of polyvalent cations is known to suppress the dissolution of silica in alkaline solutions[4]. This is perhaps the reason why the maximum decomposition
Fig. 3 The four possible exposures of the silica tetrahedra. st.=Structure.

achieved was about 94%. An experiment carried out on ash which has been previously washed with 0.5 N HCl, to remove some of the polyvalent cations, gave a maximum degree of decomposition of about 97% in the same conditions (see Table 2).

Thus, the structural state of the rice hull ash makes it superior to other forms of silica in the wet preparation of water glass. The economy of the process lies mainly in the relatively lower temperature at which reaction proceeds. Moreover, the hull—an inconvenient byproduct—can find a useful industrial application.

Table 2 Decomposition of raw ash, acid washed ash and finely powdered quartz and fused silica with NaOH solution under pressure

Type of silica	Ratio of SiO_2–Na_2O	Ratio of water–solids	Temperature (°C)	Time (h)	Decomposition (%)
Raw ash	2:1	1:1	150	1	92.7
Acid washed ash	2:1	1:1	150	1	96.8
Quartz	2:1	1:1	150	1	7.0
Fused silica	2:1	1:1	150	1	60.7

Is the vegetation of continental Antarctica predominantly aquatic ?

WE have suggested[1] that Antarctic lakes offer a more favourable physical environment to certain species of moss than the surrounding land. We now present evidence in

support of the wider thesis that in certain areas of Antarctica most of the plant biomass occurs in aquatic habitats. In the austral summer 1973–74 we found more mosses and algae growing aquatically than terrestrially in the Ablation Valley area of Alexander Island (Fig. 1). The area is relatively free from ice and has a climate similar to the inland ice-free areas of continental Antarctica[2], although conditions are not quite so arid because of frequent intrusions of oceanic weather systems from the Bellinghausen Sea. Extensive terrestrial plant cover was, however, restricted to seven discrete patches of moss, lichen and algae, totalling 2,300 m² in about 40 km² of ice-free ground searched on foot. The patches were on north-facing slopes where groundwater welled up continuously during the short summer. Widely scattered, very small moss cushions also occurred between and beneath stones in a few other damp and wet places. The availability of water and soil instability seemed to be the two most important factors restricting terrestrial plant distribution.

Many small pools, free from ice in summer, lay on ice-cored unstable moraines which bordered George VI Sound (Fig. 1). Although many pools may exist for only a few years, 95% supported a rich algal flora and associated microfauna including the calanoid copepod *Pseudoboeckella* sp.. A few pools also contained moss.

Ponds, 500–10,000 m² in area, lay between the scree-clad mountains and the moraines of ice shelf of the Sound. They became partly or completely free from ice for a short period in summer. The turbidity of the waters varied from less than 10 to more than 90% transmission per m as a result of the suspended glacial clay. In all ponds with a light transmission of more than 50% m⁻¹, luxuriant moss growth covered large areas from 0.5 to 9.0 m depth. Stems grew 30 cm in length. *Campylium polygamum* and *Dicranella* sp. were dominant. *Distichium capillaceum*, *Bryum algens* and another *Bryum* sp. were also found. Cover was estimated during SCUBA dives and varied from 40 to 80% in the 0.5 to 5.0 m depth zone and 20 to 50% overall. Total moss cover in these clearer ponds was 3,500 m² in an area of 10,000 m². Most of the remaining area was covered by rich

Fig. 1 Outline map of Alexander Island and its position in Antarctica. ———, Definite ice coastline; - - - -, approximate ice coastline. Ice shelf, stippled area. Front of ice shelf, dashed area.

algal felts growing up to 10 cm thick. Less luxuriant algal felts occurred in many of the more turbid ponds.

Three large (1.5–6 5 km²), deep (50 to more than 117 m), ice-dammed lakes lay in the main valleys. They were permanently frozen, ice cover ranging from 4.0 to 4.5 m thick in winter, 2.5 to 3 0 m thick in summer. No moss was seen in five dives covering about 10,000 m² of the bottom of the lake in Ablation Valley, and extending to 15 m depth. The only vegetation observed was a thin film of algae on the occasional rock jutting out of a silt floor. Silting alone is unlikely to have prevented moss growth because the water contained less suspended clay than some of the ponds in which mosses were abundant. The dives were carried out near the shore where the ice was more than 5 m thick and snow cover persisted for most of the summer. This may have reduced light levels below that required for moss growth. Further out in the lake where the ice was snow free and thinner, light levels may have been insufficient due to the deeper water. Mosses may have been present in other areas of this 6.5 km² lake, particularly near the north-west shore where the snow cover disappeared very early in summer. It should be noted that mosses have been found at 35 m depth in other permanently frozen lakes[3].

Contrary to our findings in the South Orkney Isands and South Georgia[1] mosses grew well in shallow water where ice scour could occur. Most of the moss must be frozen each winter. This must bring into doubt our earlier conclusion that mosses are unable to withstand ice scour. But the way ice cover melts on the Ablation ponds may differ so that ice scour is not a significant factor.

Further evidence for the predominance of aquatic vegetation in continental Antarctica is available. Rich benthic floras have been discovered in Lake Bonney[4], South Victoria Land (77°S, 161°E), lakes in the Bunger Hills[3] (66°S, 101°E) and in the Schirmachervatna[5] (71°S, 11°E). These are very arid areas free from ice where terrestrial vegetation is extremely limited.

We conclude that in such areas the vegetation may largely be confined to aquatic habitats. Consequently biologists should look more closely at aquatic habitats when carrying out surveys in continental Antarctica.

We thank Dr S. W. Greene and B. G. Bell (Institute of Terrestrial Ecology) for identifying the mosses.

Form and function in corrugated insect wings

SELECTION is likely to have resulted in the evolution of insect wings which combine aerodynamic efficiency with a rotational moment of inertia about the wing base small enough to reduce as far as possible the energy expenditure involved in their repeated accelerations. Their construction has to leave them stiff enough to remain aerodynamically efficient when under inertial or aerodynamic load, and free from buckling, however light they become. Insect wings are very light structures—11 g m⁻² in the dragonfly *Aeschna cyanea*, 16.7 g m⁻² in *Locusta migratoria*[1] and 7.4 g m⁻² in *Tipula* sp.[2].

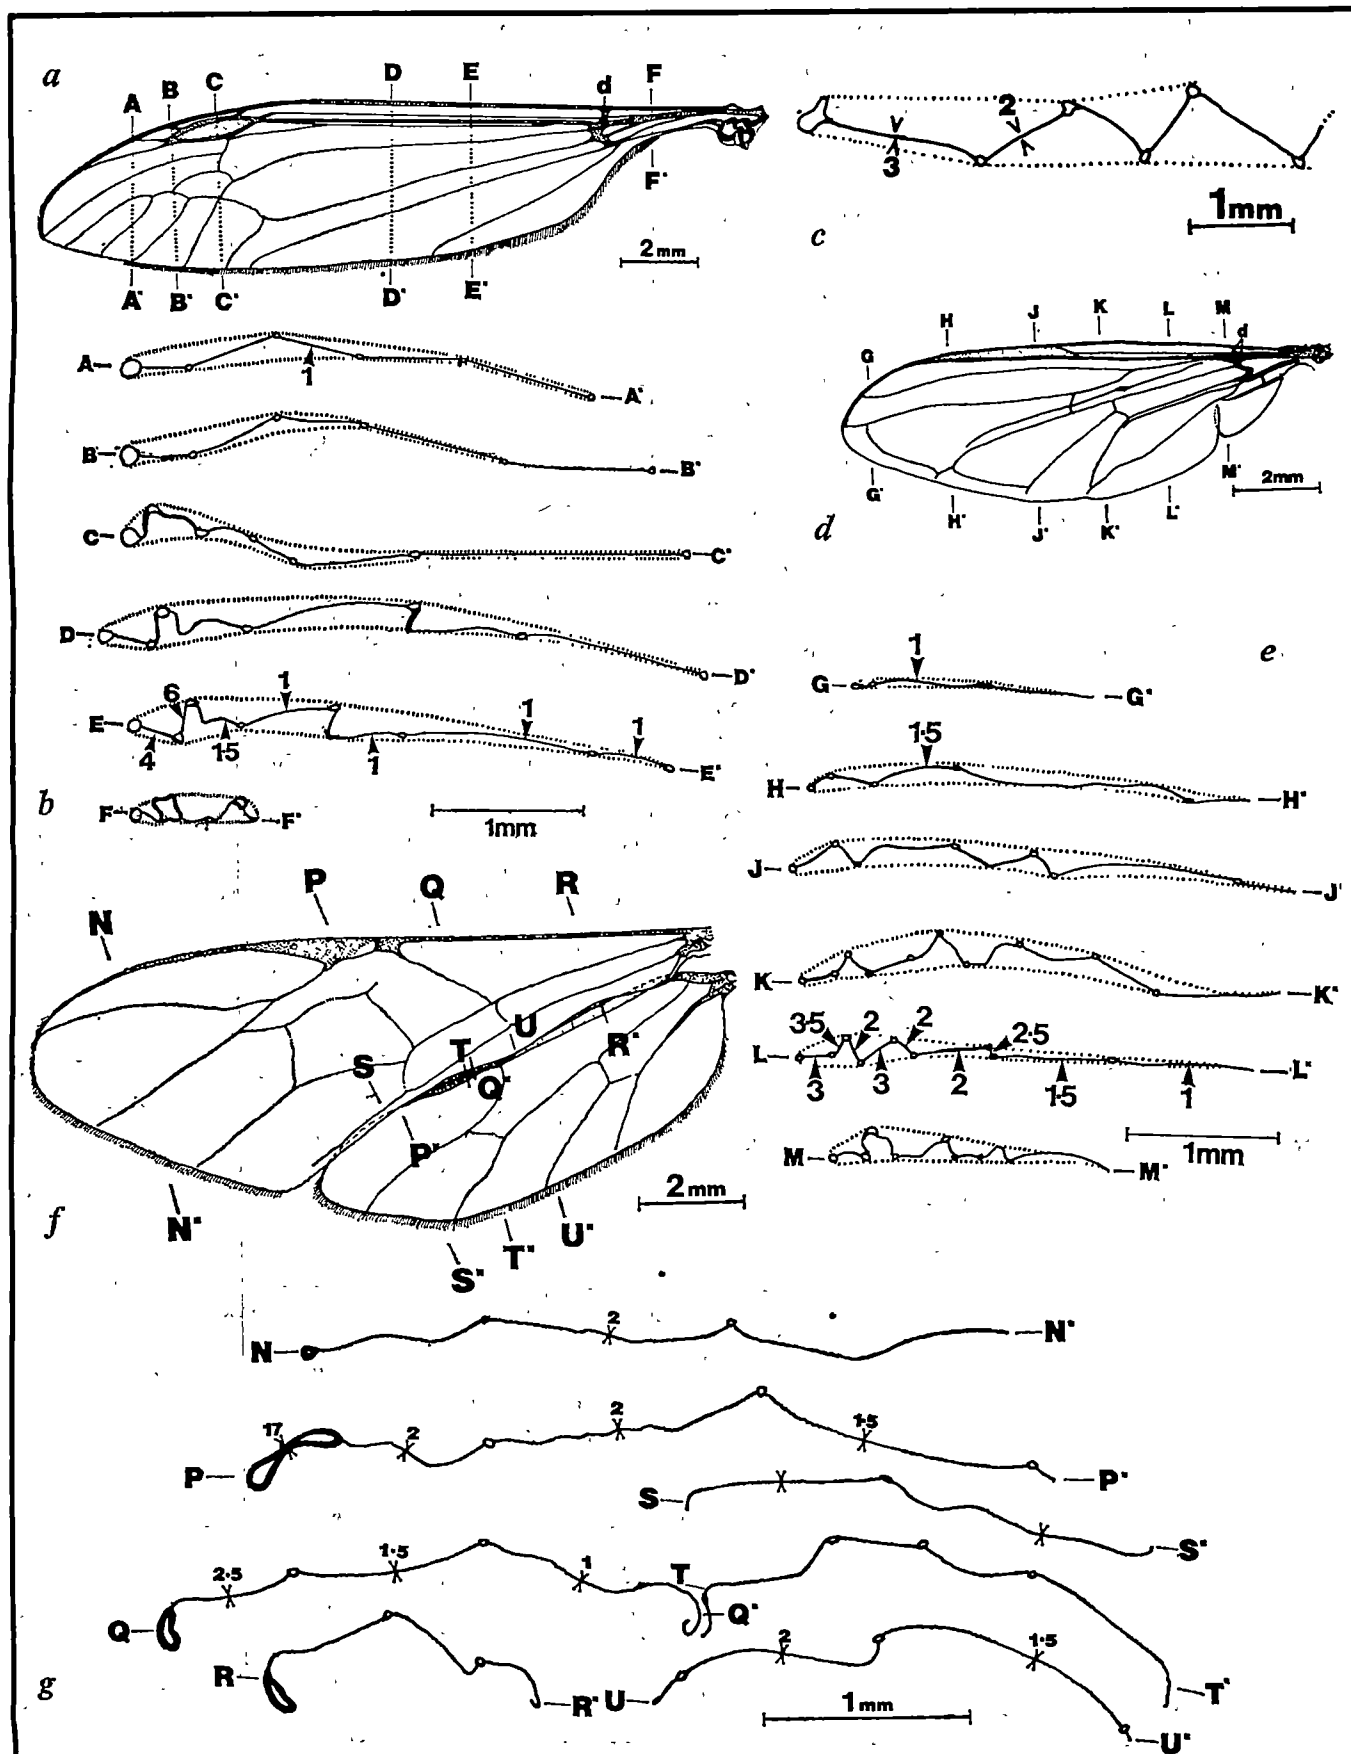
Hertel[1] has drawn attention to the corrugated chordwise profile of the anterior part of dragonfly wings, to which he attributed much of the wing stiffness, and commented on the


Fig 1 *a*, Left wing of *T. oleracea* (crane fly). d, Cuticular bar which reinforces the corrugation. Section letters apply to *b*. *b*, Chordwise sections of *T. oleracea* wing. Tubular veins to scale, membrane thickness shown diagrammatically. Some measured membrane thicknesses are shown (μm). Dotted lines, section envelopes. *c*, A section of the anterior portion of the chord of an *Aeschna cyanea* forewing (anisopteran dragonfly), redrawn from Hertel[1]. *d*, Left wing of *Syrphus balteatus* (hoverfly). d, Cuticular bar reinforcing corrugation. similarity between the disposition of the spars which form the web between upper and lower skins of an aeroplane wing, and the corrugated section of the *Aeschna* wing. In an aeroplane wing with a double skin separated by struts, however, it is the function of the struts to prevent the deformation of the smooth aerofoil profile presented by the skin, as is necessary at the higher Reynolds numbers appropriate to aircraft. In insect wings there is no enveloping 'skin' and any aerofoil properties must be sought in the corrugated wing sheet itself, operating at much lower Reynolds numbers at which the effect of corrugation on aerofoil lift and drag may not be so deleterious.

Figure 1 shows some series of chordwise sections of the wings of three insects: two dipterans (*T. oleracea* and *Syrphus balteatus*) and a hymenopteran (*Ophion luteus*). These were prepared by hand grinding thick slices cut from epoxy resin blocks, in which whole wings had been embedded, to approximately 10 μm thickness with wet carborundum paper. The embedding did not alter the corrugated form of the wings from their configuration in life; the corrugations were easily visible with either a stereomicroscope or a scanning electron microscope, where no embedding has been done. Corrugation is pronounced in both flies in most chordwise sections except those very near the wing tip. It tends to be deepest at about the one-third chord point from the leading edge, which has itself a notably rounded profile, especially in the *Ophion* wing. A somewhat similar architecture is seen in the wing of the beetle *Cicindela hybrida*[3]. Corrugation is less pronounced in *Ophion*, but the leading edge is well rounded, thickened and rigidly bent downwards.

Some comparisons of the mechanical properties of more regularly folded or tubularly reinforced beams may be relevant to a consideration of the load-bearing characteristics of insect wings. It is clear from Fig. 1 that insect wings are not beams of regular cross section, or of uniform width. They are corrugated beams of a sort, and I have therefore estimated some of the mechanical properties of a few beams of corrugated or tubulated cross section, the proportions of which are at least of the same order as those in some insect wings with respect to corrugation width, depth, membrane thickness and tube inner and outer radii. Experimental tests with metal scale models reveal that for small deflections corrugated beams which are loaded as cantilevers will behave as is predicted by simple beam-bending theory. Figure 2 summarises the dimensions of the beams which were compared, and Table 1 provides average

values of these dimensions for chordwise profiles of seven species of insects. It is hoped that these values will convey some impression of the relative cross sectional conformations of the wings of a diversity of insect species. Simple description of these profiles is otherwise difficult.
Fig. 2 *a–d*, Diagrams of parts of the cross sections of four beams the mechanical properties of which are compared in the text. *a* and *b* each show one corrugation repeat unit. NA, neutral bending axis. All other letters are those used in equations (1) to (4) in the text.

In making comparisons between regular beams, the following values were selected. The notation is as in Fig. 2, and the values apply to beams *a–d* in Fig. 2, as appropriate. Width of beams along neutral axis, $w = 1$ cm; length of beams $l = 1$ cm; $t = 1.2$ μm; $2\alpha = 112°$; $y = 0.05$ cm; $r_1 = 10$ μm; $r_2 = 4$ μm. The beams were all assumed to be made of a material similar to insect cuticle with a density of $\rho = 1.1$ g cm^{-3} and Young's modulus $E = 10^{10}$ N m^{-2} (ref. 4). Table 2 gives values of tip deflection D, maximum stress σ_M, second moment of cross sectional area I_x, mass m and rotational moment of inertia I_r about an axis passing through one end of the beam perpendicular to its length and parallel with the neutral axis and chord (Fig. 2).

The following relationships were used to compute the mechanical properties of the four beams *a–d* in Fig. 2. *F* is the force applied to the free end of the beams. $D = Fl^3/3EI_x$, $\sigma_M = Flz/I_x$, $m = \rho l A_x$ where z is the maximum distance of any part of the cross section from the neutral axis and A_x is the surface area of beam cross section. Second moments of cross

Table 1 Average values of beam dimensions for chordwise profiles in seven species of insect

Insect species	Average dimensions					Section position (mm)		
	y (cm)	t (μm)	2α (degrees)	r_1 (μm)	r_2 (μm)	A	B	
Aeschna cyanea (dragonfly) forewing	0.15	2.5	102	60	50	12.8	0.27	*

*Averaged over the corrugations in the anterior third of the chord only.

†The tubular veins are here represented by veins of U-shaped section 40 μm deep and 32 μm wide

‡These values were used in the comparisons of various regular beams. Let straight line chord length $= C$ and number of veins in the section $= N$. Average y was estimated as $y = 2(C/N - 1)$, counting the trailing edge as a 'vein'.

Average t was that of the thickness of the inter-vein membranes, measured at the mid points (chordwise) of each.

A, Distance along span of chordwise section from wing root (mm); B, fraction of total wing length which A represents.

r_1 and r_2 were average outer and inner radii for all actual veins in the cross section. Where a vein is not circular in section, the average of its maximum and minimum radii was used.

2α represents the average angle included by all pairs of membranes where they merge with a vein.

Table 2 Parameters of regular beams

$$\text{where } I_r = \int_{r=0}^{r=l} \rho A_x r^2 dr = \frac{\rho A_x l^3}{3} = \frac{m l^2}{3} \qquad (5)$$

*Deflections here will be increased by deformation under the beams' own weights, which will also increase the stress σ_M.
†Stress and deflection are expressed per 10^{-5} N applied at the free beam tip. The other ends of the beams are all fixed rigidly.

sectional area, I_x were obtained from the expressions:
For beam a:

$$I_x = \cot^3\alpha/48 \, (y^3 t \sec\alpha + 4 y t^3 \sec^3\alpha) w/y \qquad (1)$$

For beam b:

$$I_x = \{(h^3/3b^3)(c^4 + 4b^3 + 6b^2 c^2 + 4b^3 c) + \pi[((r_1^4 - r_2^4)/2) + d^2(r_1^2 - r_2^2)]\} w/y \ldots \qquad (2)$$

where $b = [(y \csc\alpha/4) - r_1 - (t \tan\alpha/2)] \csc\alpha$; $h = b \sin\alpha \cos\alpha$; $c = t \sec\alpha$.
For beam c:

$$I_x = wt^3/12 \qquad (3)$$

from Roark[5], and for beam d:

$$I_x = \left[\frac{(y - 4r_1)t^3}{12} + \frac{\pi (r_1^4 - r_2^4)}{2} \right] \frac{w}{y} \qquad (4)$$

We thus see that the introduction of corrugation is associated with scarcely any weight penalty (comparing beams a and c) although there are immense reductions both in deflection and in the maximum stress experienced for a given loading. The tubes, when added to the beam of corrugated cross section, increase its mass by a factor of 1.66, but result in a decrease in maximum stress by a factor of 2.87. Inclusion of tubes in a plane section (beam d) results in almost as great a mass as in the corrugated, tubed section (beam b), but beam d still deflects 337 times as far as beam b for a given end load, is 38 times as highly maximally stressed and yet its rotational moment of inertia I_r is only 2% less than that of beam d. What then is the function of the tubes? In a real insect wing, these tubes (veins or nervures) often carry haemolymph or serve as conduits for nerves and tracheae. In a corrugated beam with a very thin web there is in bending a tendency to collapse suddenly and catastrophically by buckling at the folds. The inclusion of tube at these positions reduces the likelihood of this form of failure.

Insect wings show irregular depth of corrugation, both chordwise and spanwise. Corrugation tends to be deeper in the anterior half of the wing, and probably reflects the chordwise distribution of aerodynamic forces. In the use of corrugated structures, there is also the problem of preventing the folds from opening out when under load. In both fly wings in Fig.1a and d there are stout chordwise bars (d) at the thoracic end of the corrugations which rigidly connect them in much the same manner as the end diaphragms in a corrugated roof to a building[6]. At the outboard end, as is seen in sections A–A[1] or G–G[1], the corrugation is hardly detectable. As such a nearly flat profile can permit virtually no further extension in a chordwise direction,

any corrugation in the wing between this flat region and the more proximal diaphragm (d) is made unable to flatten out, and the wing should retain its stiffness.

Unlike the double-skin aircraft wing, supported internally by a corrugated strut system, however, plainly corrugated wings like those of insects will have very little resistance to torsional deformation. Norberg[7] has shown, however, in dragonflies that some torsional pitching of the wing during acceleration may allow increased flight speeds, under the influence of the pitching moment of the pterostigma, and that the natural axis about which the wing twists most easily is not far from the axis of fore-and-aft mass balance of the wing. Torsional deformation of inertial and aerodynamic origin may well be very small.

Improving one's touch

DRAWING the finger tips across a smooth surface usually induces sensations of pressure, warmth or cold, and roughness or smoothness. Any abrupt discontinuity is easily felt: it has been claimed that eminences no higher than 0.001 mm etched on to smooth glass can be detected, provided some movement of the finger tips is permitted[1]. We describe here an effect which does not seem to have been reported previously, even though we think that it must be familiar to certain craftsmen.

The effect is easily demonstrated. First, rub the fingers of one or both hands back and forth across a fairly smooth surface, such as polished wood. Note the accompanying tactile sensations. Next, place a piece of paper under the fingers and rub the surface as before, moving the paper with the fingers It will be found that any gradual undulations in the surface which were hitherto undetected are now perceptible. (With practice and concentration it becomes possible to detect similar undulations without using the paper, but this is seldom as quick and easy.)

We have examined the effect in experimental conditions. A series of steel blocks, each 7.6×7.6 cm, was used. The upper surface of each block was ground smooth and flat and contained a central, raised, rectangular strip 3 mm wide. The height of the central strip varied from block to block. The central strip on each block was converted to a

gradual undulation by covering the upper surface with smooth card (0.5 mm thick) secured firmly at the edges.

Eleven subjects attempted to detect the orientation of the covered central strips by rubbing the surfaces with the fingers of one hand. On half the trials fingers alone were used, on the remaining trials a piece of writing paper was held under the fingers. The use of fingers alone compared with paper was counter-balanced across trials, as was the initial orientation of the hidden strip. Rubbing movements were made towards and away from the body; the subject was allowed to rotate the block through 90° whenever he chose. The subjects could not see the surfaces they were feeling. Twelve trials were carried out for each condition.

Performance at this task was so good, particularly when the paper was used, that we shall describe only the results obtained using the most difficult block, in which the central strip was 0.0127 mm high. Without the masking paper the orientation of the central strip on this block was correctly detected on only 59.8% of trials overall. Using the masking paper 79.5% of trials were correct. The difference in performance in the two conditions is statistically significant ($F=8.2$, $P<0.05$).

It has been established[2] that the skin contains more than one type of receptor responsive to mechanical deformation. This finding suggests a possible explanation for the effect described. If rubbing an undulating surface commonly induces more than one kind of sensory input, then a highly sensitive system, such as that associated with light pressure, may interfere with the input from deeper pressure receptors, the response to roughness thus masking the response to more gradual surface changes. The effect of placing material under the fingers may be to reduce this masking, thus allowing the appropriate input to be used in detection.

Gene dosage effect in human trisomy 16

AFTER the discovery of autosomal trisomies in man, the activity of various enzymes in trisomic cells was measured in the belief that proportionality between gene dose and enzyme activity would help in identifying genes carried by trisomic chromosomes[1-5]. It became apparent, however, that the trisomic state could produce changes in enzyme activity unrelated to gene dose, probably by interfering with normal physiological processes[6]. Therefore, verification of the concept that a simple rapport of proportionality between gene dose and concentration of secondary gene product could exist in cells with autosomal trisomy, as it does in diploid cells with gene mutations or in mouse eggs with different numbers of X chromosomes[7], had to await the recent advances in human chromosome mapping. We report here the results of a study of gene dose effects in trisomy 16.

Nine trisomic and eleven control cell strains were used to measure the activity of four enzymes: adenine phosphoribosyl-transferase (APRT, EC 2.4.2.7), which is coded by a gene on chromosome 16 (ref. 8); hypoxanthine–guanine phosphoribosyltransferase (HGPRT, EC 2.4.2.8) and glucose-6-phosphate dehydrogenase (G6PD, EC 1.1.1.49), which are X-linked; adenosine kinase (AK, EC 2.7.1.20), which is coded by an autosomal gene asyntenic with the APRT locus[9]. Cultures were set up by the plasma clot technique and grown in TC199 supplemented with 1% pooled human serum, 2% chick embryo extract and antibiotics (100 IU penicillin G and 100 μg streptomycin ml⁻¹). Stock cultures were kept in liquid nitrogen and recovered for the purpose of this study. 4×10^6 cells of each strain were collected by treatment with 0.075% solution trypsin in phosphate buffered saline (PBS), washed three times in PBS and lysed by freeze-thawing. APRT, HGPRT and AK activities were measured by the procedures of Long *et al.*[9], G6PD by the method of Giblett[10] and protein by that of Lowry *et al.*[11]. ¹⁴C-hypoxanthine, ¹⁴C-adenosine and ¹⁴C-adenine were obtained from the Radiochemical Centre, Amersham and ATP, TTP, phosphoribosyl pyrophosphate, NADP and glucose-6-phosphate from Sigma.

on the specimens used in this study is summarised in Table 1.

Assays showing a linear relationship between enzyme activity and extract dilution were used for analysis (Fig. 1).

Enzyme assays (Table 2) showed a 69% increase in APRT activity in trisomic cells. Such an estimate has wide confidence limits and does not differ significantly from the 50% increase expected on the hypothesis of direct and linear proportionality between gene dose and enzyme activity. In contrast, HGPRT, AK and G6PD activities do not differ significantly in trisomic and control cells.

As HGPRT and G6PD are X-linked[12,13], we tested whether their activities are influenced by the number of X chromosomes present in the cells—either directly by comparing the levels of

Fig. 1 Graphs showing relationship between cell extract dilution and enzyme activity in a typical experiment. Trisomic (●) and control (○) cell strains were recovered in pairs. When both strains had reached confluency the cells were collected and assayed together to minimise variations caused by the phase of cell growth and the conditions of the assays. Aliquots from the same cell extract were used to assay all the four enzymes and all but G6PD were tested concurrently and in duplicate on three serial dilutions of the cell extract. *a*, HGPRT; *b*, APRT; *c*, AK.

enzyme activity in male and female trisomic and control strains or indirectly by comparing the differences in enzyme activities of controls and trisomic cells in pairs of equal sex and pairs formed by a male trisomic and a female control (last seven in Table 2). These tests indicate that the activities of these two enzymes do not differ significantly in male and female control or trisomic cell strains (Table 3).

Past experience suggests caution in the interpretation of increased enzyme activity in trisomic cells. Note that changes in enzyme activity unrelated to gene dose have usually been observed in blood cells. The latter are in a terminal state of differentiation and are usually tested immediately after their withdrawal from the abnormal environment of the trisomic subject. In this study, trisomic and control cells were grown for some time in vitro in identical conditions and analysed in the same growth phase.

Because changes in enzyme activity for physiological rather than strictly genetical reasons may similarly affect enzymes of related metabolic pathways, APRT activity was compared with that of the metabolically related enzymes, HGPRT and AK. In fact the ratio of HGPRT to APRT activity has already been profitably and extensively used in the measurement of gene dose effects in euploid cells—namely, the detection of heterozygotes for mutations at the HGPRT locus[14-16]. The genes coding for the enzymes considered in this work are well expressed in interspecific somatic cell hybrids and seem, therefore, rather insensitive to abnormal genetic situations. In view of these considerations we believe that our observed increases in APRT activity in cells with trisomy 16 is the direct expression of gene dose and is not secondary to a change in cell physiology. Our findings, therefore, provide some evidence for a linear and directly proportional relationship between gene dose and enzyme activity.

A dosage effect for the two loci assigned to chromosome 21 has also been reported in Down's syndrome. Sinet et al.[17] have observed a 40% increase in the activity of the cytoplasmic form of superoxide dismutase (SOD-1) in erythrocytes of patients with trisomy 21. Unfortunately, however, they have not studied the activity of other enzymes or tested SOD-1 in other types of cells. The value of their observation is, therefore, greatly

reduced by the fact that erythrocytes in Down's syndrome have repeatedly shown increases in the activity of enzymes not coded by chromosome 21. Tan et al.[18] have studied the relationship between gene dose and the production of antiviral protein (AVP) in trisomy 21 by measuring the antiviral protection afforded by this protein to trisomic cells. AVP activity is induced by interferon and cells with trisomy 21 have been shown to be three to seven times more responsive to such induction than cells with trisomy 13 or 18, or normal chromosome complement. It is at present unclear whether the nonlinear relationship observed between AVP gene dose and antiviral protection reflects the effect of gene dose on protein synthesis or that of AVP concentration on viral infection. The answer to this dilemma and comparisons between the behaviour of inducible and constitutive enzymes in cells with abnormal karyotypes may help us to understand, in biochemical terms, the phenotypic effect of chromosome imbalance.

Table 3   Sex differences in HGPRT and G6PD activity in trisomic and control cells

	HGPRT activity		G6PD activity	
	Difference	Probability	Difference	Probability
Control cells (♂ against ♀)	−4.3	>0.5	0.063	>0.1
Trisomic cells (♂ against ♀)	0.68	>0 5	−0.077	>0.1
Pairs of equal sex against pairs of unequal sex*	6.2	>0.2	0.028	>0.1

* Only pairs of unequal sex comprising a male trisomic and a female control are considered.

Our HGPRT and G6PD assays seem to support the evidence for dosage compensation of X-linked genes in man by suggesting that compensation takes place even in 8–14-week-old zygotes, whose development has been severely impaired by trisomy 16.

We thank Dr E. Alberman, Mr M. R. Creasy and Mr J. A. Crolla for foetal cell strains, and Professor P. E. Polani for

encouragement and advice. This work was supported by the Spastics Society and by an anonymous gift.

Why didn't Gregor Mendel find linkage?

IT is quite often said that Mendel was very fortunate not to run into the complication of linkage during his experiments. He used seven genes and the pea has only seven chromosomes. Some have said that had he taken just one more, he would have had problems. This, however, is a gross oversimplification. The actual situation, most probably, is shown in Table 1. This shows that Mendel worked with three genes in chromosome 4, two genes in chromosome 1, and one gene in each of chromosome 5 and 7. It seems at first glance that, out of the 21 dihybrid combinations Mendel theoretically could have studied, no less than four (that is, *a–i*, *v–fa*, *v–le*, *fa–le*) ought to have resulted in linkages. As found, however, in hundreds of crosses and shown by the genetic map of the pea[1], *a* and *i* in chromosome 1 are so distantly located on the chromosome that no linkage is normally detected. The same is true for *v* or *le* on the one hand, and *fa* on the other, in chromosome 4. This leaves *v–le*, which ought to have shown linkage.

Mendel, however, seems not to have published this particular combination and thus, presumably, never made the appropriate

Table 1 Relationship between modern genetic terminology and character pairs used by Mendel

Character pair used by Mendel	Alleles in modern terminology	Located in chromosome
Seed colour, yellow–green	*I–i*	1
Seed coat and flowers, coloured–white	*A–a*	1
Mature pods, smooth expanded–wrinkled indented	*V–v*	4
Inflorescences, from leaf axils–umbellate in top of plant	*Fa–fa*	4
Plant height, >1m–around 0.5 m	*Le–le*	4
Unripe pods, green–yellow	*Gp–gp*	5
Mature seeds, smooth–wrinkled	*R–r*	7

cross to obtain both genes segregating simultaneously. It is therefore not so astonishing that Mendel did not run into the complication of linkage, although he did not avoid it by choosing one gene from each chromosome.

Defect of macrophage function in the antibody response to sheep erythrocytes in systemic *Mycobacterium lepraemurium* infection

THE need for macrophages for optimal antibody responses, both *in vivo* and *in vitro*, to certain antigens is now established[1,2] and this paper describes experiments which have used this requirement to demonstrate a deficiency of macrophage function in mice experimentally infected with the rodent leprosy bacillus, *Mycobacterium lepraemurium*. This organism is an obligate intracellular dweller and is found particularly inside cells of the macrophage series although in terminal infection other cell types may be invaded. Systemically infected mice characteristically show macrophages overloaded with bacilli, ever increasing numbers of granulomata and increasing spleno- and hepatomegaly[3]. There is an increase in the phagocytic activity of the spleen and liver at an early stage of infection (I.N.B and V S.S., in preparation) indicative of alterations in macrophage function and we report here experiments which show that the *in vivo* and *in vitro* antibody response to sheep erythrocytes (SRBC) is depressed at later stages of infection. The results indicate a defect of macrophage function.

Young adult CBA female mice were injected intravenously with 10^9 *M. lepraemurium* freshly isolated from the heavily infected livers of mice infected 4–6 months previously (I.N.B. and H. N. Krenzien, in preparation). At 11–15 weeks after infection, when the present experiments were carried out, the mice appeared clinically healthy but at autopsy showed gross enlargement of liver and spleen. Ziehl-Neelsen stain revealed the presence of numerous mycobacteria in macrophages of various tissues, particularly liver, spleen and bone marrow. Uninfected mice of the same age and sex were used as controls The *in vivo* antibody response was measured in mice injected intravenously with either 5×10^6 or 10^9 SRBC. Four days later, the number of antibody producing cells (PFC) present in the spleen of each mouse was determined using the method of Cunningham[4]. The *in vitro* response of spleen cells cultured for 4 d according to the method of Marbrook[5] was measured in the same way.

The results given in Table 1 show that the antibody response *in vivo* was reduced 11 weeks after infection and even more so at 14 weeks. This depression was more pronounced in animals injected with the smaller number of SRBC. It seemed greater when the results were expressed as PFC per 10^9 spleen cells because there was a 4–5-fold increase in the cellularity of the spleens from infected compared with normal mice. Serum antibody levels were also reduced in infected mice (results not shown). Spleen cells from infected animals cultured *in vitro* in the presence of SRBC failed to generate the expected number of PFC, particularly at 14 weeks.

Table 1 Antibody response of mice, or spleen cells from mice, infected with *M. lepraemurium*

Parameter of response	Dose of SRBC	Control	Weeks after infection	
			11	14
In vivo				
$\log_{10}$ PFC per spleen	5×10^6	5.85 ± 0.02	5.33 ± 0.06	4.87 ± 0.16
	10^9	5.97 ± 0.04	5.76 ± 0.07	5.28 ± 0.03

Spleen cells were cultured in RPMI 1640 medium containing HEPES, bicarbonate and 5% foetal calf serum. The cultures contained 20×10^6 spleen cells and 2×10^6 SRBC. The values shown are means $\pm$ s.e. of four mice in each group or quadruplicate cultures of spleen cells pooled from two or three mice. The significance of difference between control and experimental groups, calculated using the two-tailed Student/Welch's t-test[6], was at the level of $P < 0.005$ or higher.

Further studies were carried out *in vitro* to obtain information about the functional status of macrophages and lymphoid cells in infected spleens. Cells from infected and control mice were fractionated into adherent (macrophage) and non-adherent (lymphocyte) populations and were then cultured in various combinations in the Marbrook system. The results are shown in Table 2. Cultures containing only non-adherent cells produced small numbers of PFC and no PFC were detected in cultures of peritoneal cells or adherent spleen cells (not shown in the table). When non-adherent cells from the spleens of normal mice were supplemented with normal peritoneal cells or adherent

spleens were supplemented with either normal peritoneal cells or normal spleen adherent cells (experiments 2 and 3).

The results presented here indicate, in contrast to another report[9], that the antibody response to SRBC is depressed in mice systemically infected with *M. lepraemurium*. Furthermore, the defect was associated particularly with the macrophages of infected animals and not with their lymphocytes at the stages of infection studied. Our experiments do not indicate a direct contact effect by heavily infected macrophages or the release of a suppressive factor. The nature of the defect has yet to be established. Two possibilities are being considered in our immediate experi-

Table 2 The *in vitro* antibody response of spleen cells from mice infected with *M. lepraemurium*

Experiment	Cells cultured	PFC per culture		
			Weeks after infection	
		Control	11	14–15
1	Spleen unfractionated	$2,140 \pm 82$	960 ± 57	620 ± 22
2	Spleen non-adherent + normal PC	$2,140 \pm 85$	$1,790 \pm 78$	$1,466 \pm 33$
3	Spleen non-adherent + normal spleen adherent	$1,886 \pm 41$	$1,800 \pm 26$	$1,706 \pm 63$
4	Spleen unfractionated + normal PC	$2,600 \pm 10$	$1,716 \pm 51$	$1,510 \pm 59$
5	Spleen non-adherent	190 ± 12	96 ± 46	80 ± 34
6	Normal spleen non-adherent + infected spleen adherent	—	$1,192 \pm 64$	610 ± 13

Cultures of unfractionated spleen cells contained 20×10^6 cells ml^{-1}. Non-adherent cells were obtained by incubating spleen cells (20×10^6 ml^{-1}) twice for 30 min at 37 °C on glass and the free cells in the suspension were then gently agitated and poured off and 1 ml put into each culture vessel. The adherent spleen cells were removed from the glass surface by means of a rubber policeman before which the surface was vigorously washed with fresh medium. Peritoneal cells (PC) were obtained by washing the peritoneal cavity of untreated mice. Cultures were supplemented with macrophages by adding 2×10^6–3×10^6 viable adherent spleen cells or 4×10^6 peritoneal cells. All cultures contained 2×10^6 SRBC. Values given are means $\pm$ s.e. of quadruplicate cultures.

spleen cells (experiments 2 and 3), the PFC response was similar to that found in cultures of unfractionated normal spleen cells. This result confirms earlier findings[7,8] on the requirement for macrophages in the primary response to SRBC *in vitro*. On the other hand, when adherent cells from the spleens of mice infected 11 or 14–15 weeks before were used to supplement non-adherent normal mouse spleen cells (experiment 6) the number of PFC found in the cultures was similar to that found in cultures of unfractionated spleen from infected animals (experiment 1). This result suggested that macrophages from infected mouse spleens were defective in some respect or, alternatively, that they had an inhibitory effect on the function of lymphocytes. These possibilities were tested by adding normal mouse peritoneal cells to cultures of unfractionated spleen cells from normal or infected animals (experiment 4). Under these conditions, the PFC response of the cultures prepared from infected animals was substantially improved (compare experiments 1 and 4) indicating that the presence of infected macrophages did not greatly interfere with the PFC response provided that adequate numbers of normal macrophages were present.

Further evidence for the essentially normal function of the lymphoid cells of infected mice was obtained from experiments where non-adherent cells from infected mouse

ments. First, that overloading of macrophages with mycobacteria may interfere with their ability to ingest, process and present other antigens in a normal manner[10], and second, a possibility associated with the massive antibody production against *M. lepraemurium* antigens during infection, that antigen–antibody complexes are formed and become bound to the surface of macrophages, thus blocking the sites for binding of the factor(s) produced by T lymphocytes which may be required for antibody production to SRBC. Whether or not macrophage defects of a similar nature occur in diseases of man where macrophage involvement is extensive, for example, leprosy, leishmania and malaria, requires further study. If they do, they could account, at least in part, for the immunosuppressed state often associated with such infections.

Promotion of cell fusion by divalent cation ionophores

THE importance of cytoplasmic calcium has recently been emphasised by demonstrations that the ionophores X537A and A23187, which are known to facilitate the movement of Ca^{2+} through membranes[1,2], trigger secretion in the presence of extracellular calcium ions[3,4]. We now report observations on the effects of these two cation ionophores on hen erythrocytes at physiological *p*H, which raise the possibility that the phenomenon of cell fusion may also be mediated by an increased concentration of cytoplasmic Ca^{2+}.

A suspension of hen erythrocytes (about 6×10^8 cells ml^{-1}) in buffered solution (A), (NaCl 116 mM, $CaCl_2$ 1 mM, Me_2AsO_2Na 10 mM, glucose 1 g l^{-1}, penicillin G 200,000 units l^{-1}, streptomycin sulphate 100 mg l^{-1}; *p*H 7.4) was prepared[5]. After centrifugation, 1 ml of the packed cells was incubated with 250 units of neuraminidase solution (*Vibrio cholerae*) (0.5 ml; Behringwerke AG) for 30 min at 37 °C. The treated cells were then washed twice with the buffered salt solution (10 ml), diluted to give a cell suspension of $\sim 6 \times 10^8$ cells ml^{-1}, and kept at 4 °C until used later on the day of preparation.

Suspensions of neuraminidase-treated cells ($\sim 2 \times 10^8$ cells ml^{-1}) in buffered salt solution (A) containing dextran (80 mg ml^{-1}; MW 82,000; Sigma Chemical Co.), were incubated at 37 °C with either X537A or A23187 (6.6 µg ml^{-1}). X537A and A23187 were given by Roche Products and Eli Lilly respectively. The ionophores were dissolved in ethanol (1 mg ml^{-1}). Small aliquots of cell suspension were removed at intervals for microscopy. In control experiments, neuraminidase-treated cells were incubated with ethanol (6.6 µl ml^{-1}) in the dextran-containing medium, free from ionophore.

After treatment with neuraminidase, the erythrocytes aggregated into large clumps on incubation at 37 °C with dextran, and the outlines of individual cells in these clumps could not easily be distinguished (Fig. 1*a*). A similar dextran-induced aggregation has been reported to occur with neuraminidase-treated human erythrocytes[6]. When ionophore was also present, individual cells in the clumps became rounded and swollen within 15 min. The nuclei were clearly visible in these preparations and limited cell fusion may have occurred after 3 h (Fig. 1*b*). A further incubation of the cell suspensions at 47 °C for 10 min resulted in extensive fusion (Fig. 1*d*). Essentially similar results were obtained with both ionophores. Without ionophore, the neuraminidase-treated, dextran-aggregated cells were apparently unaffected after 30 min further incubation at 47 °C (Fig. 1*e*). Electron microscopy confirmed cell fusion in the cells treated with ionophore (Fig. 1*c*), but no fusion was seen in its absence. Only a limited degree of cell fusion occurred, even at 47 °C, when the concentrations of ionophores were reduced tenfold (0.66 µg ml^{-1}).

A first requirement for cell fusion is cell contact. In the presence of lysolecithin hen erythrocytes aggregate and fuse at *p*H 5.6 (ref. 7). With fusogenic lipids, for example glyceryl mono-oleate, fusion at *p*H 5.6 is facilitated by dextran which increases the aggregation of hen erythrocytes treated with the fusogen[5]. Following neuraminidase action, the cells are more rapidly fused even at *p*H 7.4 by glyceryl mono-oleate, in the presence of dextran[8]. Divalent cation ionophores seem to have little aggregating action and, for fusion to occur rapidly, it seems to be necessary to treat the cells with neuraminidase and then to aggregate them with dextran. Cell fusion occurred, however, in the presence of 2 mM Ca^{2+}, even at 37 °C, with hen erythrocytes that were not pretreated with neuraminidase but were incubated in dextran-containing media for 5 h with A23187 or 18–22 h with X537A.

Membrane fluidity is also important in cell fusion[8,9], and changes in membrane structure resulting from treatment with X537A and A23187 that lead to cell fusion are markedly accelerated by raising the temperature to 47 °C. (Thermally induced cell fusion at 48–50 °C and *p*H 5.6 in the absence of ionophore, which was reported earlier[8], occurs only on a heated, microscope stage and not with cells in free suspension.) Alternatively benzyl alcohol (30 mM), which increases membrane fluidity[10] but is not fusogenic at this concentration[11], may be used instead of heat to aid the induction of cell fusion by ionophore. Mechanical tapping of a microscope slide
Fig. 1 *a, b, d* and *e,* Light micrographs (phase contrast, ×300) of neuraminidase-treated hen erythrocytes at *p*H 7.4 prepared as described in the text. *a,* A clump of aggregated cells formed on incubation at 37 °C for 5.75 h with dextran (80 mg ml^{-1}) and ethanol (6.6 µl ml^{-1}). *b,* Swollen, aggregated cells arising on incubation at 37 °C for 3 h with dextran (80 mg ml^{-1}), ethanol (6.6 µl ml^{-1}), and X537A (6.6 µg ml^{-1}). *d,* Cells treated as in *b* followed by incubation at 47 °C for 10 min: multinucleated syncytia are present that contain aggregated nuclei, and areas of nuclei-free cytoplasm (arrows). *e,* Cells treated as in *b,* but without ionophore, followed by incubation at 47 °C for 30 min. *c,* An electron micrograph of a thin section, prepared as described previously[7], of cells that were incubated at 37 °C for 1 h with dextran (80 mg ml^{-1}), ethanol (6.6 µl ml^{-1}), and A23187 (6.6 µg ml^{-1}), followed by 45 min at 47 °C, showing two nuclei in a common cytoplasm: vacuolation of the plasma membrane is also apparent (×8,250).

bearing a preparation like that shown in Fig. 1b will also trigger some of these cells to fuse.

Light microscope experiments provided no evidence that either valinomycin (6.6 μg ml^{-1}), with or without 2,4-dinitrophenol (0.1 mM), or 2,4-dinitrophenol alone caused the erythrocytes to fuse. Increasing the concentration of Ca^{2+} from 1 to 3 mM allowed the changes, including cell fusion, caused by X537A and A23187 to occur more rapidly, but was without effect on cells treated with valinomycin or valinomycin and DNP. The actions of X537A and A23187 with 1 mM Ca^{2+} were inhibited by EGTA and EDTA (2 mM); inhibition by the chelating agents was overcome by excess Ca^{2+} (final concentration 3 mM). It may therefore be concluded—as with secretory systems[3,4]—that the observed fusogenic action of these two divalent ionophores is mediated by entry of Ca^{2+} into the cells.

Ca^{2+} probably facilitates cellular aggregation in cell fusion. On the basis of our experiments it is also conceivable that Ca^{2+} may mediate cell fusion, occurring either naturally or in response to fusogenic agents[5], by interacting with the cytoplasmic side of the plasma membrane following an initial increase in membrane permeability to exogenous Ca^{2+}. This would apparently be contrary to the views of Poste and Allison[12] who have postulated that membranes can exist in two states, (1) the normal Ca^{2+}-associated state; and (2) the "fusion susceptible" state in which Ca^{2+} has been displaced from the membrane.

Cell swelling, which accompanies fusion induced by ionophores and lipid fusogens[5], may be a result of inhibition by cytoplasmic Ca^{2+} of membrane-bound Na$^+$/K$^+$-dependent ATPase activity, with a resultant loss of cytoplasmic potassium[13], and the entry of external water as postulated for the Ca^{2+}-dependence of the acrosome reaction[14]. Ca^{2+} may also be expected to aggregate negatively charged spectrin molecules on the cytoplasmic surface: this will, in turn aggregate integral membrane proteins[15]. Furthermore the binding of Ca^{2+} to phosphatidylserine molecules in a membrane yields solid aggregates that allow other phospholipids to form fluid clusters[16]. If this should occur at the cytoplasmic surface of the erythrocytes, where most of the phosphatidylserine is located[17], it would probably also lead to an aggregation of intramembranous proteins[18]. Aggregation of membrane proteins[12,19] and the clustering of lipid molecules[19] are thought to be important in membrane fusion. These phenomena may therefore all participate in cell fusion induced by an increase in the concentration of cytoplasmic Ca^{2+}. Some of these suggestions may also be relevant to the Ca^{2+}-mediated fusion of membranes that occurs in secretory processes[20,21].

Differential formation of desmosomes and hemidesmosomes in epidermal cell cultures treated with retinoic acid

IN various epithelial tissues, desmosomes (D) as well as the hemidesmosomes (HD) are common specialisations of the plasma membrane[1]. Both membrane differentiations are thought to play an important role either in cell–cell adhesion (D) or in the attachment to biological substrata (HD)[2]. *In vitro* formation of D and HD has been observed in embryonic lens cells[3] or organ culture outgrowth of skin[4]. We have now found that in cultured post-embryonic epidermal cells (PEC) both membrane specialisations are formed independently of each other. We show that in cells stimulated to grow, an increased number of attachment devices contacting the substratum is formed. At the dorsal surface of the same cell, however, morphological expression of tissue-specific differentiation is present.

In cultured PEC (ref. 5), nuclear DNA synthesis as well as cellular growth is greatly enhanced by the addition of retinoic acid (RA) to the culture medium. Comparison with other cell systems present in skin indicates tissue specificity[6]. The mitogenic effect of RA was therefore used to study the formation of membrane specifications under different growth conditions.

Figure 1 shows that numerous specialisations of the plasma membrane are present in 3-d-old cultures. HD are exclusively present at the underside of 'basal' cells contacting the plastic substratum. On the other hand, D are located at the upper side of 'basal' cells facing overlying epidermal cells. The morphology of both, HD and D, does not seem to be different from previous *in vivo* descriptions[1,2].

Twice as many HD were present at the undersurface of RA-treated cells by comparison with controls ($P < 0.005$, Fig. 2). Functionally, this greater number of HD present in treated cells should indicate increased adherence to the substratum. Considerably longer exposure times to trypsin are necessary, however, to collect RA-treated cells as compared with untreated controls (E. C. and H. H. W., unpublished).

The number of D at the dorsal site of the 'basal cell' plasma membrane contacting the suprabasal cell did not change with treatment (Fig. 2). Obviously, within the same cell the site-dependent attachment devices are formed independently.

In epithelial cells freshly treated with trypsin, D and HD are absent[3], and are therefore most likely to be newly formed during cellular reaggregation. Also, formation of D depends on the presence of adjacent cells of the same species and of a corresponding maturational age[3]. Our observed distribution of both membrane specialisations follows the *in vivo* pattern of epidermal differentiation.

In contrast to tumour cells, so-called 'normal' cells show strong anchorage dependence when grown *in vitro*[7]. It has been found[8] that changing the substratum (from glass to agarose) under otherwise identical conditions resulted in

decreased adherence of cells, reduced rate of DNA synthesis and increased generation time. It thus seems that in normal cells attachment to the substratum is linked to cellular proliferation.

There is evidence that in epidermal cells such fixation to the substratum is provided by hemidesmosomes. Our observation of a greatly increased number of HD in rapidly multiplying cells supports the concept that these membrane specialisations are positively correlated with cell proliferation. Under *in vivo* conditions strong adherence to the basal

Fig. 2 Number of HD (*a*) and D (*b*) in 3-d-old cultures of PEC treated with 10 µg ml^{-1} RA (hatched bars) and untreated controls (open bars). Epon-embedded specimens were obtained after *in situ* fixation of entire culture plates. Selected areas were excised and cut with a diamond knife. Vertical sections were stained with uranyl acetate and lead citrate, and viewed with a Philips EM300 microscope. Photomicrographs were taken for HD and D counts at magnifications between 8,000 and 26,000. Length of plasma membrane on both sides of the cells was measured using a map roller. HD and D were counted and the results calculated as HD or D per 10 µm surface length + s.e.

lamina would thus be provided for cells engaged in reduplication.

On the other hand, upward movement and tissue-specific differentiation of epidermal cells coincides with the disappearance of hemidesmosomes and increased formation of desmosomes. The basic functional difference between the two attachment devices of the epidermal cell membrane thus seems to be closely linked to the mechanism of epidermal cell renewal.

Fig. 1 High density epidermal cell culture grown *in vitro* for 3 d (control). Two types of membrane specialisations are formed: D, located at sites in contact with adjacent cells (*a*), and HD, exclusively present at the undersurface of cells contacting the substratum (*b*). Cultures were prepared[5] by gentle treatment with trypsin of adult guinea pig ear skin fragments. Cell suspensions consisting of single cells were seeded at a density of 1.8–2.2 × 10⁶ ml^{-1} in 35 mm Falcon culture dishes and maintained in 5% CO_2–air at 37 °C. *trans*-Retinoic acid (Nordmark-Werke, Uetersen) was dissolved in DMSO and added to the culture medium (McCoy 5a, supplemented with 10% foetal calf serum, penicillin and streptomycin) at a final concentration of 10 µg ml^{-1}. The concentration of DMSO in all cultures, including controls, was 0.1%. *a*, ×27,540; *b*, ×60,000.

Demonstration of intermolecular forces in cell adhesion using a new electrochemical technique

THE problem of cell adhesion has been approached from both chemical[1-3] and physical[4,5] viewpoints. We present here new evidence that a purely physical attraction acts between cells and other surfaces and that electrostatic forces can overcome this attraction. Previous attempts to demonstrate

and interpret such forces[6-8] have largely been frustrated by inadequately defined test surfaces, biological media including complex macromolecular components, and inappropriate assays for cell adhesion.

The unique features of our experimental approach are that the interfacial electrostatic charge of a well defined clean metallic surface can be varied continuously from positive to high negative values, and measured accurately. We have consequently been able to determine the critical electrostatic condition for cell adhesion. Another significant feature of our system is that the very low contamination rate of the test surface can be monitored continually during the course of the experiment.

We have used the relatively new development of solid polarisable electrodes: the test surface was a lead electrode[9] whose high polarisability in contact with electrolyte enables the interface to be charged positively or negatively by means of a battery and potentiometer: the magnitude of the charge being determined accurately from differential capacitance measurements. Since a current density of only a few $\mu A\ cm^{-2}$ flowed across the electrode surface, the experiment was virtually electrostatic. The lead surface was prepared by chemical polishing, after which it is probably molecularly smooth over large areas. Contamination of the electrode by oxygen, the adsorption of ions or organic molecules, could be detected by capacitance changes, providing a criterion for the rejection of poorly prepared electrodes. In practice, high stability over a 6-h period was frequently achieved following exhaustive cleaning and deoxygenation of the entire system.

We examined the adhesion of glutaraldehyde-fixed human red blood cells to the electrode in dilute sodium fluoride solutions of electrochemical purity. Aldehyde fixation, which has little or no effect on cell surface charge[10], was necessary to render cells stable at low ionic strength and to avoid loss of cellular proteins which might otherwise contaminate the electrode. Adhesion was assessed by allowing cells to settle for twenty minutes (settling for a period of 1 h does not affect the results) on to the polarised electrode and then inverting it while under continuous microscopic observation: cells which fell off were scored as non-adhesive. Cell falling was usually completed in 10 min.

In 10 mM NaF all cells stuck to the electrode, even at high negative surface charge. As the concentration was reduced to 1.1 mM, however, a most interesting pattern of behaviour was seen. When the electrode was positively charged ($+1.2 \times 10^3$ e.s.u. cm^{-2}) the negatively charged cells adhered irreversibly—our criterion for irreversibility being that the cells continued to adhere when the negative polarisation was subsequently increased to the maximum value of -4.1×10^4 e.s.u. cm^{-2}, approximately ten times the cell surface charge density. But when cells were allowed to settle on the negatively polarised electrode, within the range -5×10^3 to -3×10^4 e.s.u. cm^{-2}, reversible adhesion occurred. The cells failed to fall off when the electrode was inverted even after 20 min, but within a few minutes of the negative polarisation being increased beyond -3×10^4 e.s.u. cm^{-2} most of the cells were forced off electrostatically and were seen to sediment away from the electrode under the effect of gravity. Cells which adhered to the electrode at different charge densities within the range -5×10^3 to near -3×10^4 e.s.u. cm^{-2} fell off close to the critical charge density of -3×10^4 e.s.u. cm^{-2}.

The explanation for these entirely novel observations can be provided in terms of electrostatic and electrodynamic forces. The physical force theory[5] predicts strong, probably irreversible, adhesion at the limit of molecular approach (primary potential energy minimum) and a weaker reversible adhesion where cell and surface are separated by a finite gap and the forces of attraction and repulsion are equal (secondary potential energy minimum), the two energy minima being separated by an energy barrier.

Preliminary calculations suggest that the distance of closest approach between a red cell and the metal surface may be several hundred Å in the secondary minimum position. We therefore feel that the essential criteria for the duplex adhesive behaviour predicted by the physical force theory have been demonstrated, and it is hard to think of an alternative explanation for the experimental facts. It is anticipated that when the distance of separation between cell and electrode has been measured directly it will be possible to estimate the size of the attractive force from the repulsion and make a quantitative comparison with the theory.

Whether secondary minimum adhesion occurs in physiological conditions remains uncertain. In our experimental system it has been found only at very low ionic strength where electrostatic repulsion can be maximised. But the calculated electrodynamic attraction to metal is large[5], so that lower repulsion coupled with lower attraction may give reversible secondary minimum adhesions in physiological media. Further experiments on cell adhesion at charged oil–water interfaces[11] may answer this question.

Our experiment has demonstrated that attractive forces which presumably include both image forces and electrodynamic (van der Waals') forces, and repulsive electrostatic forces, all of which can act over distances greatly in excess of chemical bond lengths, are responsible for the adhesive behaviour of red blood cells to a defined surface in the most stringently controlled conditions yet used in such work. The very nature of these rigorous controls makes the experiment unavoidably non-physiological; this, however, by no means detracts from the fact that long range interactions have been shown to occur between the complex architecture of protein, lipids and glycoprotein comprising the cell periphery, and the atoms of a solid surface. The conclusion that these forces also operate between cells would seem to be unavoidable.

Increased spontaneous transmitter release from presynaptic nerve terminal by methylmercuric chloride

IN recent years, several incidences of methylmercury pollution have been documented[1,2], one of the most striking alterations induced by the compound being extensive damage to the nervous system. Experimental mercury poisoning has been produced in animals[3,5], detailed morphological studies of which have shown that acute changes occur initially in the peripheral nerve fibres and thereafter in the central nerve cells[3,4]. Little

is known, however, about functional changes in the nervous system, particularly in the initial stages of poisoning. This report describes one possible target site—the synaptic transmission in the sympathetic ganglia—for methylmercury poisoning. The study is also of interest, as a number of heavy metallic ions such as La^{3+}, Co^{2+} and Mn^{2+} have recently been reported to have profound effects on neuromuscular transmission[6-9].

solution. Table 1 summarises the results together with those from untreated control animals. Values for the resting potentials and amplitudes of the action potentials were within the control ranges. There was no sign of impairment of impulse transmission from the preganglionic nerve to ganglion cells (Fig. 1a and b). Amplitudes of the spontaneous miniature excitatory postsynaptic potentials (MEPSPs) were also unaffected, but frequencies were increased significantly (Fig. 1c and d), their

†Amplitudes of the action potentials evoked by the preganglionic nerve stimulation.
‡Velocities of the most rapidly conducting impulses in the preganglionic nerve, approximated by an estimation from latency of the first EPSP and distances between stimulating and recording electrodes.

Superior cervical ganglia with the preganglionic nerve fibres isolated from guinea pigs (160–240 g) were used. Preparations were mounted in a constant temperature bath (34–36 °C) perfused with a modified Krebs solution, as described previously[10]. A single microelectrode filled with 0.6 M K_2SO_4 was used to record intracellularly the membrane potential of individual ganglion cells. The preganglionic nerve fibres were stimulated with twin platinum electrodes to evoke orthodromic responses in ganglion cells.

In the first series of experiments, each guinea pig was given 1 mg methylmercuric chloride (CH_3HgCl) intraperitoneally in aqueous solution. Inspection of the animals at any time after injection revealed no neurological symptoms of the mercury poisoning, such as an ataxic gait or a crossing phenomenon in the hind limbs, reported to occur in rats when total doses of the administration amounted to more than 10 mg (ref. 3). At 30 min, 1, 5, 12 and 30 d after injection, ganglia were isolated and measurements of the electrical activities made in normal

Fig. 1 a, Typical record of action potential and EPSPs in response to three successive stimulations of preganglionic nerve, from an intact guinea pig. b, As a, but killed 30 min after intraperitoneal injection of 1 mg CH_3HgCl. c, Typical record (continuous from top to bottom) of MEPSP from intact guinea pig. d, As c, but 30 min after injection. Note increase in frequency of MEPSP in record d. Calibration, 10 mV and 10 ms for records a and b; 5 mV and 0.1 s for records c and d. Records retouched.

mean values within 5 d of injection being 240–500% greater than control. After 12 d, there was a similar increase in the mean value, but no statistical significance. This is probably caused by a large variability in values for individual ganglion cells. After 30 d, the increased frequency returned to the control level.

In patients suffering from effects of Niigata methylmercury pollution in Japan, Kanbayashi et al.[11] have found a significantly reduced value for the velocity of the most rapidly conducted impulse in the motor nerves. On the other hand, Von Burg and Rustam[12] have found negative results in the patients of an outbreak in Iraq. In agreement with the latter, our study shows no significant change in the velocity of the preganglionic nerve (Table 1).

Thus, the first series of experiments shows that one of the earliest manifestations of CH_3HgCl poisoning with small doses could be detectable as an increase in spontaneous transmitter release from the preganglionic nerve terminal, and that the animal recuperates within a relatively short time after such poisoning.

In the second series of experiments, isolated ganglia from intact animals were exposed continuously to a solution of CH_3HgCl (0.04 mM; 10^{-5} g ml^{-1}). Fig. 2a, recorded in normal solution, shows a typical MEPSP occurring at a frequency of 0.13 s^{-1}. Figure 2b, recorded 10 min after exposure to the test solution, shows a sudden appearance of unusually large spontaneous potentials, the largest reaching 13.6 mV at an increased frequency of 4.40 s^{-1}. In three cells tested, average amplitudes (± s.d.) were increased from 0.6±0.1, 1.3±0.6 and 1.2±0.5 mV in normal solution to 7.1±4.3, 7.6±4.8 and 3.3±1.0 mV after exposure, respectively. We cannot readily explain, however, the appearance of the large MEPSPs. An anticholinesterase-like effect of CH_3HgCl can be ruled out, because the time course of the large MEPSPs was not prolonged. One possibility is that the compound may depolarise the preganglionic nerve terminals and trigger action potentials leading to release of large amounts of transmitter. At 15 min after exposure (Fig. 2c), the frequency of MEPSPs was further increased (in the three cells tested, 0.13, 0.13 and 0.12 s^{-1}, in normal solution, to 18.89, 21.20 and 25.60 s^{-1} after exposure, respectively). Some action potentials were initiated from the MEPSPs (Fig. 2c). Amplitude and configuration of the action potentials were similar to those evoked in normal solution by preganglionic nerve stimulation, indicating little effect of the compound on the postsynaptic cell membrane. At 20 min after exposure (Fig. 2d), the frequency gradually decreased.

Fig. 2 a–e, Application of CH_3HgCl, 0.04 mM, to a ganglion cell by perfusion. a, Normal solution; b–e, 10 min, 15 min, 20 min and 40 min after exposure. f–j $HgCl_2$, 0.04 mM. f, Normal solution; g–j, 30 min, 45 min, 80 min and 90 min after exposure. All records, except h and i, continuous from top to bottom. h and i, upper straight line shows zero potential. Calibration, 5 mV and 0.1 s for a, b. e, f, g and j; 10 mV and 0.1 s for c, d, h and i. See text for explanation. Records retouched.

At 40 min after exposure (Fig. 2e). MEPSPs ceased. At that time, the preganglionic nerve stimulation could not evoke any response in the ganglion cell, indicating that progress of the impulse to nerve terminals was blocked, and/or the transmitter substance was completely exhausted by the compound.

For comparison, similar experiments were carried out with an inorganic mercury compound $HgCl_2$ (0.04 mM; 1.34×10^{-5} g ml^{-1}) (Fig. 2f–j). $HgCl_2$ also caused increases in amplitude and frequency of the MEPSPs (Fig. 2g). Compared with CH_3HgCl, however, the increases were smaller and appeared after much longer exposure (more than 25 min). In three cells tested, amplitudes were increased from 1.5 ± 0.5 to 2.6 ± 1.2, 1.5 ± 0.9 to 3.4 ± 2.3 and 1.7 ± 0.4 to 2.0 ± 0.8 mV, and the frequencies from 0.28 to 6.14, 0.07 to 2.38 and 0.36 to 0.78 s^{-1} after exposure. At 45 min after exposure (Fig. 2h), the cell was gradually depolarised and underwent repetitive firing for more than 10 min. Further exposure (Fig. 2i) resulted in sustained depolarisation of the membrane to about 30 mV, and the firing ceased leaving only a local fluctuation (similar to a response) in the membrane potential. Eventually, 90 min after exposure, the cell became electrically silent (Fig. 2j).

Thus, it has been shown in in vitro experiments that the primary site of CH_3HgCl action is on the presynaptic nerve terminal, from which rapid and large spontaneous transmitter release occurs. $HgCl_2$ actions are both presynaptic, resulting in the release of relatively small quantities of transmitter, and postsynaptic, resulting in the sustained depolarisation of ganglion cells. In conclusion, mercury compounds, particularly CH_3HgCl, resemble the La^{3+} ion which is reported to cause also a rapid and large increase in the frequency of miniature endplate potentials in frogs[6].

We thank Professor I. Tanaka for guidance, Professors T. Morioka and T. Isa for advice, and Dr T. Inoue for CH_3HgCl.

Chemotactic stimulation by cell surface immune reactions

CHEMOTAXIS of migratory leukocytes is of special interest to immunologists as it is intimately associated with tissue reactions initiated by immune responses. Chemotactic activity as measured in vitro with the Boyden chamber has been exclusively associated with chemotactic factors of various origins which all have in common the inherent ability to attract the responding cells. Immune-related chemotactic factors attracting neutrophils (polymorphonuclear leukocytes, PMNs) and macrophages are either complement (C)-derived as a result of C activation or they are products of activated lymphocytes. Thus, their activity is secondary to a specific humoral or cellular immune reaction taking place independent of and at a distance from the responding cell. Here we present a new concept of chemoattraction in which the chemotactic stimulus is a direct result of an immune reaction that proceeds on the surface of the responding cell itself. This concept originated from the discovery of the chemotactic stimulation of PMNs by cytotoxic sera at subcytotoxic doses.

This phenomenon was first observed in heterologous systems, nurse shark and dog sera cytotoxic for human PMNs (refs 1 and 2), and then for homologous systems, human and dog anti-sera against histocompatibility antigens that were cytotoxic for human and dog PMNs, respectively, (J A. J., and V. E., unpublished). The conditions in which chemotaxis was observed in these cytotoxic systems are shown in Fig. 1a, b and c. We interpreted these results to mean that cytotoxic immune reactions can cause an 'irritation' at the cell surface acting as a chemotactic stimulus provided at least one of the necessary reactants (antibody or the C system or even one limiting C component) is presented to the responding cell on a positive concentration gradient. In the following we show that cells carrying
Fig. 1 Schematic representation of different modes of chemotactic stimulation by cell surface immune reactions. cytophilic antibody can be chemoattracted by the specific antigen. This situation could be of great biological significance, and is illustrated in Fig. 1*d*.

English short hair female guinea pigs (600 g) were immunised intracutaneously at three sites with a total of 3 mg crystalline ovalbumin in Freund's complete adjuvant. Two to three weeks later they were injected intraperitoneally with 30 ml 0.1% shell-fish glycogen in saline. After 4 h the animals were bled, killed and their peritoneal PMNs collected in heparinised saline. The cells were washed and, without further preparation, used in the chemotactic assay.

The cell preparations were usually 98% pure. The upper chamber compartment received 2×10^6 PMNs in Gey's medium.

From Table 1 the following conclusions may be drawn: PMNs from immunised animals were chemotactically attracted by the antigen, whereas those from controls were not. PMNs from normal, non-immunised animals, if treated with immune serum, behaved like cells obtained from immunised animals; if treated with preimmune serum they behaved like normal cells. Antigen introduced into the upper compartment of the chamber together with the cells did not increase random movement that could be mistaken for chemotaxis (R. Snyderman, personal communication). The chemotactic response was dependent on the antigen concentration (dose–response). Chemoattraction by the antigen could only be clearly demonstrated if normal guinea pig serum was present at low concentrations in the upper compartment (or in both compartments) of the chemotaxis chamber. Adding the serum to the upper compartment only had two major advantages: if the serum contained any chemotactic factors they would form a negative concentration gradient for the cells; and possible interactions of serum constituents with the chemotactic antigen were minimised.

We are not yet sure whether the requirement for serum in the medium represents C participation in the given circumstances. This possibility is under investigation. As regards the nature of the responsible antibodies, we have preliminary evidence that the responding cells, obtained from immunised animals or from normal animals and treated with immune serum, carry easily detectable antibody on their surface, whereas controls do not. We are probably dealing with cytophilic (homocytotropic) antibodies. It should be mentioned that the chemotactic response was antigen-specific, that is, that an unrelated antigen (bovine serum albumin, BSA) did not chemoattract the cells carrying anti-ovalbumin antibodies.

In considering the mechanism of this kind of chemotaxis, it is tempting to compare it with the phenomenon of hista-

IGP, immunised guinea pig; NGP, normal (non-immunised) guinea pig; CHP, cells per high power field. *In vitro* chemotaxis was carried out and quantified as described[3]. Modified Boyden chambers were set up in triplicate. Results are expressed as average number PMN per high power field on lower surface of Millipore filters (5 μm pore size) separating the upper from the lower compartments of the chambers. Gey's medium was used throughout. Incubation time 3 h, temperature 37 °C in water saturated 5% CO_2 in air. Cells from non-immunised animals were divided and one half was treated for 45 min at 4 °C with homologous immune serum at the indicated final dilution in Gey's medium; the other half was treated in the same way with the corresponding preimmune serum. All cells were thoroughly washed in Gey's medium before they were placed in the upper compartments. Negative controls contained no antigen in the lower compartments. Chemotactic responsiveness of the cells was ascertained for each experiment. In all experiments except that marked by * the upper compartments contained 0.5% normal autologous guinea pig serum. The last five experiments (lower part of table) were quantified by measuring the distance (in μm) that the migrating cells had travelled into the filter[4].

mine release or degranulation exhibited by mast cells on contact of antigen with their cytophilic antibodies. The same kind of signal that induces this dramatic effect could well cause a migratory cell to move in the direction of its stimulated surface area.

We believe that this new concept may have several important implications under *in vivo* conditions: if wandering cells, carrying cytophilic antibody, can be attracted to the origin of antigen release, whether the antigen is microbial or derived from allogenic tissue or tumour cells, their accumulation at that site would then not only depend on C activation or the formation and release of chemotactic factors by proliferating lymphocytes. This mechanism, for instance, could contribute to the development of an Arthus reaction in C4-deficient guinea pigs (refs 5 and 6); it could also be the basis for the immune-mediated emigration of neutrophils into the lumen of the small intestine, observed in pigs sensitised with BSA (ref. 7)

We had an opportunity to test our views in clinical rather than experimental conditions A patient with a long history of dermatophytosis (*Trichophyton rubrum*) was by mistake skin-tested with an excessive dose of dermatophytin, and within 30 min developed a severe local reaction with increasing induration, erythema and pain accompanied by general malaise and fever. The reaction, which began to subside after 48 h, was Arthus-like, although there was no histological confirmation. The patient's peripheral PMNs isolated 2 and 8 weeks after the incident were strongly chemoattracted by dermatophytin, whereas PMNs from individuals negative to the skin test were completely unaffected by the antigen.

As preliminary experiments in our laboratory and elsewhere (P. C. Wilkinson, personal communication) conducted with macrophages are in agreement with the data reported here for PMNs, we believe that our concept of antigen chemotaxis may be a rather general one. We propose, therefore, as a hypothetical extension of our findings, that lymphocytes (of the B as well as the T-cell series) may also be chemoattracted to the site of the antigen that they are specifically equipped to recognise. The same signal that results in the turn-on of the cell on interaction of its surface recognition molecules with the antigen may also result in its directional migration. This hypothesis would endow the concept of immunological surveillance with an active search and guiding system instead of the chance encounter on which it is now based

Control of acetylcholinesterase by contractile activity of cultured muscle cells

THE activity of the enzyme acetylcholinesterase (AChE) is one of the many properties of skeletal muscle known to be regulated by nerves. For example, AChE is synthesised and released by chick embryo muscle fibres grown *in situ* and in culture[1,2]. During maturation *in situ*, neural activity decreases AChE everywhere in the muscle fibres of chicks

except at the neuromuscular junction[3]. How nerves repress this extrajunctional AChE is not known. The possibility that they do so by signalling the muscles to contract, and that muscle contractile activity itself reduces the level of enzyme, has been tested by extracellular stimulation of muscle cultures with electrical impulses. Our results indicate that contraction reversibly reduces AChE activity of muscle cultures.

Muscle cultures were obtained from 11-day chick embryo pectoral tissue by trypsinisation and the cells were cultured in collagen-coated dishes in a medium of 10% horse serum, 2% embryo extract and 88% minimal essential medium (MEM)[2]. The fibres exhibited spontaneous contractions and cross striations after 5 d in culture and were readily maintained for 3 weeks *in vitro*.

Electrical stimulation resulted in decreases in the AChE of the cells and the AChE released into the medium (Table 1) In each of eight experiments the AChE activity was lower for stimulated than for unstimulated cultures. The average reduction of AChE activity of the cells was 37%. The decrease observed for the AChE released by the cells was even more pronounced, averaging 61%. The total decrease in AChE of the cultures varied with a range of 30% to 90%.

Since denervation increases AChE activity in chicken muscle fibres *in situ*[4], we investigated whether AChE activity would increase when electrical stimulation ceased. The data (Table 2) show that AChE increased after stimulation, indicating that suppression of AChE activity

A Grass S8 stimulator was connected in series to a pair of platinum electrodes approximately 25 mm long and 3 mm wide. The electrodes were attached to the top of a culture dish and immersed in the culture media. Six dishes in series were given a 100 mm s⁻¹ train consisting of three 10-ms pulses repeated every 5 s. The voltage was approximately 30 V, the minimum that produced contractions of >75% of the fibres as determined with an inverted phase contrast microscope. Stimulation was continued for 48 h and polarity was switched frequently to minimise effects of electrolysis.
*AChE activity was determined spectrophotometrically by the Ellman assay[10] using the pseudocholinesterase inhibitor iso-OMPA as in previous reports [1–3].

*Values are means of ± s.d. of six dishes for experiment 1 and three dishes for experiments 2–8.

†Cell activity 48 h after stimulation minus cell activity immediately after stimulation.

‡Statistically significant difference between unstimulated and stimulated cultures $P<0.02$ for experiments 2–8. Differences are not significant ($P>0.10$) for experiments 1–8. (Student's t test[11].)

was reversible. In addition, except for the first experiment, cell AChE and release of AChE in the medium tended to be greater 48 h after stimulation for previously stimulated than for unstimulated cultures.

The increase of AChE activity after stimulation was also evidence that stimulation did not injure the cells. Furthermore, the cells were still contracting and were morphologically unchanged when observed by light microscopy after 48 h of stimulation. Also, the ability of the cultures to synthesise protein was not affected. Incorporation of ^{3}H-leucine[2] (ICN Pharmaceuticals, 10 μCi per culture in leucine-free MEM) into trichloroacetic acid precipitates of cultures labelled for 1 h after stimulation gave an average in four experiments of 38,000 c.p.m. for stimulated cultures and 36,000 c.p.m. for unstimulated cultures.

We reasoned that if muscle activity were involved in regulating AChE, cultures unable to contract would produce more AChE than those contracting spontaneously Tetrodotoxin (a drug that blocks excitation of the membrane of muscle fibres in culture[5]), 0.1 mg per dish, was added to 5-d-old cultures and the cells were maintained in a non-contracting state for 6 or 8 d. The cells and media were sampled every 2 d and the total AChE produced over the entire period was compared for the relaxed and the contracting cultures (Table 3). The non-contracting tetrodotoxin-treated cultures produced much larger amounts of AChE, averaging 218% the activity of the spontaneously contracting cultures.

Stimulation has also been shown to affect ACh sensitivity *in situ* and ACh receptors in culture. Drachman and Witzke[6] and Lømø and Rosenthal[7] reduced the spread of ACh sensitivity over the membrane of denervated rat muscles and Cohen and Fischbach[5] reduced the extrajunctional ACh receptors of embryo muscle cultures by means of electrical stimulation. When considered together, these reports and the data presented here strongly suggest that some regulatory actions of nerve on muscle are mimicked by stimulation and may be due to muscle activity. particularly with regard to extrajunctional localisation of

Table 3 Effect of tetrodotoxin on AChE of muscle cell cultures

molecules involved in transmission at the neuromuscular junction. Whether contractions themselves are necessary or whether excitation of the muscle membrane would suffice is a matter for further investigation. There is evidence that muscle activity[8] and cholinergic transmission[9] may not be required for localisation of ACh receptors at the neuromuscular junction. Therefore, it is possible that there are separate regulatory mechanisms for extrajunctional and endplate AChE and ACh receptors.

Presence in brain of a mitogenic agent promoting proliferation of myoblasts in low density culture

NORMAL animal cells in tissue culture proliferate very slowly, or not at all, when their density is less than 20 cells mm^{-2} (ref. 1). This property of density-dependent cell proliferation has long been a major obstacle to establishing clonal cultures. Conditioned media[4] or feeder layers[2,3] have been used to promote proliferation of single cells in culture. We have reported the presence, in bovine pituitary and brain, of a mitogenic factor, fibroblast growth factor (FGF), that can control the rate of growth of animal cells *in vitro*[5] We report here that the proliferation of myoblasts
Fig. 1 *A*, DNA synthesis in BALB/c 3T3 cells in response to various concentrations of brain crude extracts prepared at diverse *p*H. Crude brain extracts were produced by homogenisation of bovine brains at 4 °C in 0.15 M $(NH_4)_2SO_4$. The *p*H was adjusted to either 3.0, 4.0, 4.5, 7.0 or 8.5 and the homogenate was stirred for 2 h at 4 °C, and centrifuged at 23,000*g*. The supernatant was dialysed, centrifuged and then lyophilised. FGF was prepared as described previously[5,6]. 3T3 cells were plated in Dulbecco's modified Eagle's medium (DME) with 10% calf serum (4 × 10⁴ cells per 35 × 15 mm dish with 2 ml medium per dish). After 1 d the medium was removed and replaced by DME with 0.1% calf serum. Two days later various concentrations of samples dissolved in the presence of 0.5% crystalline bovine serum albumin (to minimise nonspecific adsorption) were added to the cultures. Determinations of the incorporation of ³H-thymidine into DNA were carried out as described previously[5]. ○, *p*H 4.0; ▲, 4.5; □, 3.5; ●, 7.0; △, 8.5. *B*, Effect of brain crude extracts obtained at different *p*H on the proliferation of myoblasts seeded at low density. Myoblasts were obtained from foetal calf (at 3 months gestation) by trypsinisation of the thigh muscle as described previously[12]. The resulting cell suspension was plated on to three 15-cm plastic tissue culture dishes (Falcon) in 1:4 DME–medium 199 supplemented with 10% foetal calf serum and 1% chick embryo extract, then incubated at 37 °C in a humidified incubator in an atmosphere of 5% CO_2 in air. After 1 d the medium was renewed and 5 µg ml⁻¹ cytochalasin B was added to select for myoblasts as described by Sanger[13]. The next day, the myoblasts were shaken loose from the dishes by gentle agitation, and the resulting suspension was centrifuged. The pellet was suspended in 1:4 DME–medium 199 with 10% horse serum. The cells were then plated at a final concentration of 300 cells per 6-cm gelatinised dish in 5 ml 1:4 DME–medium 199, with 10% horse serum. The brain crude extracts obtained at diverse *p*H were added 24 h later to a final concentration of 100 µg ml⁻¹. Similar numbers of clones were observed when the extract was added at the time of seeding or 1 d later. The dishes were incubated for 14 d (control) and 7 d (experimental) without a change of medium or further additions. After rinsing and fixing, the dishes were stained with crystal violet. *a*, Control; *b*, *p*H 3.5; *c*, 4.0; *d*, 4.5; *e*, 7.0; *f*, 8.5. Note the formation of myotubes in *e* and *f*.

seeded at low densities can be greatly accelerated by low concentrations of brain or pituitary crude extracts. This myoblast growth factor (MGF) is distict from FGF.

The effect of brain crude extracts prepared at diverse *p*H on the initiation of DNA synthesis in 3T3 cells maintained in low serum is shown in Fig. 1*a*. Extracts prepared at *p*H 4.0 or 4.5 were the most potent, and those prepared at *p*H 7.0 and 8.5 were essentially free of activity. In contrast, when the diverse crude extracts were tested on sparse, primary cultures of myoblasts maintained in 10% horse serum, the most active extract was that prepared at *p*H 8.5. The *p*H 7.0 extract was less active than the *p*H 8.5 (Fig. 1*b*).

As the mitogenic (FGF) activity for 3T3 cells is extracted preferentially at *p*H 4.5, whereas the activity responsible for the growth of myoblasts maintained at very low density in the presence of 10% serum is best extracted at *p*H 8.5, the activities are, very likely, distinct.

Ion-exchange chromatography provided further evidence that MGF activity was distinct from FGF. When a *p*H 8.5 crude extract of brain was applied on a CM Sephadex column equilibrated with 0.1 M sodium phosphate, *p*H 6.0, MGF activity was unadsorbed. In the same conditions, the FGF activity was retained[6]. When the *p*H 8.5 crude extract of brain was applied on a DEAE-Sephadex column equilibrated with 0.05 M sodium phosphate, *p*H 7.6, MGF activity was retained and the FGF activity was unadsorbed. This indicates that MGF is a neutral polypeptide compared with FGF, which is basic.

The effect of the *p*H 8.5 brain crude extract on the rate of proliferation of myoblasts seeded at 300, 100 and 50 cells per 6-cm dish was measured (Fig. 2). After 14 d, little growth had taken place in the control, although the cells had been maintained in the presence of 10% horse serum. In contrast, when the myoblasts were maintained in 10%

horse serum plus 100 µg ml⁻¹ of *p*H 8.5 extract, extensive proliferation took place in all cases. Extensive differentiation, as reflected by the formation of myotubes, was also observed (Fig. 3). In 70% of the colonies, striated myotubes formed and in 20% of the colonies, syncytium formation was noticed. This suggests that crude extract not only promotes cell proliferation, but also promotes differentiation, as more than 75% of the nuclei were in myotubes.

When the myoblasts were maintained in the presence of FGF, proliferation was stimulated, but not to as great an extent as with crude extract of brain. Furthermore, the colonies did not differentiate into myoblasts as extensively as those with brain crude extract added. When myotubes were present in a colony they did not contain more than two to five nuclei per myotube (Fig. 3).

Pituitary crude extracts had an effect similar to that of brain crude extracts and FGF purified from pituitary had an effect similar to FGF from brain.

Chick embryo extract promoted the proliferation of myoblasts seeded at low density, although the effect was small when compared with brain crude extract (Fig. 4).

As NIH pituitary preparations, such as luteinising hormone (LH) and thyroid-stimulating hormone (TSH), have been reported to contain mitogenic contaminants[7,8], the effects of several NIH preparations on myoblast proliferation were compared. Of the various preparations tested, follicle-stimulating hormone (FSH) and gonadotrophic hormone had the least activity. LH of either ovine or bovine origin and TSH, however, had considerable growth-promoting activity. Insulin, which has been reported to promote cell proliferation *in vitro* when present at high concentrations, was inactive on myoblasts seeded at low density (Fig. 4).

In conclusion, we have reported that crude extract of
Fig. 2 Comparison of effects of brain crude extract (*p*H 8.5) and FGF on proliferation of myoblasts seeded at low density. Cells (300, 100 or 50) were plated in 6 cm dishes in 5 ml 1:4 DME–medium 199 with 10% horse serum. Brain crude extract (100 μg ml^{-1}) and FGF (1 μg ml^{-1}) were added 24 h later. Controls did not receive any additions and no change of medium was carried out during the incubation. Controls were incubated for 7 d. After 7 d, the myotubes in the dishes in the presence of brain crude extract started to contract rythmically and detached, preventing further incubation. *a*, 300 cells; *b*, 300 cells plus 100 μg ml^{-1} brain extract, *p*H 8.5; *c*, 300 cells plus 1 μg ml^{-1} FGF; *d*, 100 cells; *e*, 100 cells plus 100 μg ml^{-1} brain extract, *p*H 8.5; *f*, 100 cells plus 1 μg ml^{-1} FGF; *g*, 50 cells; *h*, 50 cells plus 100 μg ml^{-1} brain extract, *p*H 8.5; *i*, 50 cells plus 1 μg ml^{-1} FGF. Note the formation of myotubes in *b*, *e* and *h* and their apparent absence in *c*, *f* and *i*.

brain prepared at *p*H 8.5 contains potent mitogenic factor(s) for myoblasts seeded at low density. The observation that those factors for myoblasts can be selectively extracted at high *p*H, whereas FGF, soluble at low *p*H, is reminscent of the situation for polypeptide hormones; some are most soluble at low *p*H, whereas others are most soluble at high *p*H (ref.9).

In addition to its mitogenic effect, the *p*H 8.5 brain crude extract also promoted the formation of myotubes. In that respect it seems to act as a differentiating agent similar to those present in conditioned medium used for promoting

the fusion of chick myoblasts[10,11]. In contrast, FGF, although it was less potent than the *p*H 8.5 crude extract, promoted proliferation of myoblasts but not extensive fusion. This observation agrees with the suggestion that FGF is an agent which promotes proliferation but delays fusion (our unpublished work).

The observation that, at *p*H 8.5, additional mitogenic agents other than FGF can be extracted from the brain may be of technical use for cloning cells or for accelerating the growth of the cells that divide slowly.
Fig. 3 Clones of myoblasts (×10) grown in presence of either brain crude extract, *p*H 8.5, or FGF. *a*, Clone grown in the presence of brain crude extract, pH 8.5 (100 μg ml^{-1}). Cells (300) were seeded in a 6 cm dish giving rise to colonies. Shown is a clone arising from one of these cells after 10 d. Note extensive network of myotubes, very well differentiated. Some of the myotubes contain as many as 1,000 nuclei. In some instances, presence of a loose syncytium was observed. *b*, Clone grown in the presence of FGF (1 μg ml^{-1}). Original plating was as described for *a*. Clone contained mostly single cells, with some forming short myotubes with two to three nuclei (arrows).

Capacity of foetal spinal cord obtained from dystrophic mice (*dy²J*) to promote muscle regeneration

RECENTLY Gallup and Dubowitz[1] described a series of tissue culture experiments in which they attempted to clarify the part played by the motor neurone in the pathogenesis of murine muscular dystrophy. Bishop *et al.*[2] had shown that muscle explants obtained from human subjects grew nor-

mally in Carell flasks. Gallup *et al.*[3] reported similar results with muscle explants of trypsinised minced muscle obtained from dystrophic chick that had been grown *in vitro* on collagen-coated surfaces in Petri dishes. They were unable to differentiate between cultured normal and dystrophic muscle. But they reported significant differences between cultures of normal mouse cord with either normal or dystrophic muscle and dystrophic cord with either normal or dystrophic muscle. When contacted by ventral root neurites from normal spinal cord, the muscle cells of both normal and dystrophic muscle fused to form new fibres with well developed cross striations and peripherally located nuclei. The appearance of both normal and dystrophic muscle coupled with 'dystrophic' spinal cord was quite different. The initial cellular regenerative response was followed in most cases by degeneration and disappearance of all muscle elements, leaving only strands of connective tissue. In only three out of thirteen cultures were myotubes formed, and these failed to develop synchronised contractions.

On the basis of this evidence, Gallup and Dubowitz[1] concluded that the lesion causing murine dystrophy in muscle is primarily neurogenic.

Their results partly contradict our own observations[4] that normal and dystrophic muscle can regenerate equally well in the presence of foetal spinal cord obtained from either normal or dystrophic mice. In an attempt to explain the apparent contradiction, we have examined the procedure applied by Gallup and Dubowitz[1]. It occurred to us that Gallup and Dubowitz[1] may possibly be reporting results obtained in their small samples mainly from cultures of lumbar spinal cord. In our previous investigations we randomly coupled cross sections from all levels of the cord

with adult muscle. It seemed imperative, therefore, to determine whether the suspected neurogenic lesion of the dystrophic mutant might initially be located in the lumbo-sacral portion of the cord. Since the dystrophy in the *dy* mouse is progressive and starts in the muscles of the hind limbs which are innervated by lumbo-sacral fibres, the possibility that a difference in the procedures may be responsible for the contradictory results could not be excluded.

To test this hypothesis, cervical, thoracic and lumbar foetal cord from 15-d-old mouse embryos homozygous for dystrophy dy^2J/dy^2J were explanted and within 5 d coupled to normal tibialis muscle as well as to dystrophic tibialis muscle obtained from young adult mice.

Our attention was focused on the capacity of different levels of spinal cord to stimulate regeneration of muscle. In particular, the purpose of this experiment was to determine whether the lumbar and sacral portion of 'dystrophic' cord differs from cervical and thoracic cord in its ability to promote differentiation of regenerated muscle strips coupled with it in culture.

The experimental technique relied essentially on a tissue culture system in which spinal cord and muscle fragments from normal and dystrophic mice were explanted in close proximity to each other, that is, 'coupled'. Dystrophic mutant mice C57BL/6J dy^2J supplied by the Jackson Laboratory, Bar Harbor, Maine, and raised in our laboratory were used.
Fig. 1 *a*, Whole mount preparation of a culture of normal muscle coupled to dystrophic cord cervical level *in vitro* 50 d with phosphotungstic acid haematoxylin stained (PTAH); ×380. *b*, Same as *a* coupled to dystrophic cord thoracic level, 50 d *in vitro*, stained with PTAH; ×380. *c*, Same as *a* coupled to dystrophic cord lumbar level, 60 d *in vitro*, stained with PTAH; ×380. *d*, Same as *a* coupled to dystrophic cord sacral level, 60 d *in vitro* stained with PTAH; ×380.

Spinal cords were dissected from foetal mice aged 13–14 d *in utero*. After laminectomy, cervical and lumbar cord with its meningeal covering and attached dorsal root ganglia (DRG) were obtained from the foetuses. Complete cross sections of the spinal cord with their occompanying DRG (ref. 5) were explanted on to collagen-coated coverslips[5,6] provided with a drop of nutrient fluid, and sealed into a Maximow double coverslip assembly. The nutrient medium which was renewed twice a week consisted of 33% human placental serum, 10% chick embryo extract (9 d), 50% Eagle's minimal essential medium (MEM), 7% balanced salt solution, and was supplemented with 600 mg% glucose and 1.32 ml⁻¹ of acromycin. Cultures were incubated at 34–35 °C in the lying-drop position, and observed regularly by bright field microscopy employing a long-working distance, ×40, oil immersion objective.

Phenotypically dystrophic mice were obtained from matings between tested homozygotes for the dystrophic gene dy^2J. Young adult mice homozygous for dystrophy and normal mice served as donors for muscle explants. Strips of muscle fibres were explanted near 4- to 5-d-old spinal cord cultures[5,6]. The following combinations were

studied: (1) normal cords and normal muscle; (2) cervical, thoracic, lumbar and sacral levels of cord obtained from foetuses homozygous for the *dy* mutations coupled to normal tibialis muscle (Fig. 1).

Normal muscle coupled with either normal or *dy* foetal spinal cord regenerated in culture. Innervation of the muscle explants led to gradual increases in fibre size and the development of cross striations. Spontaneous synchronised contraction occurred intermittently.

Fragments from all levels of the spinal cords from dystrophic foetal mice were as effective as were normal cords in inducing regeneration and innervation of muscle.

These results clarify some of the conflicting evidence reported in the literature. They confirm our earlier observations[4], that both normal and dystrophic muscle can regenerate in the presence of either normal or dystrophic cord. These results were most recently confirmed by Parson[7].

The conflicting observations reported by Gallup and Dubowitz[1] may be due to a statistical sampling error. Their conclusion that muscular dystrophy is determined solely by the spinal cord and that the neurones in the spinal cord are by themselves capable of producing the myopathy is far from proven.

Several investigators have reported that electron microscopy *in vitro* material revealed abnormalities in motor endplates were present, however, both in muscle fibres numbers and distortions of synaptic vesicles[8]. In cultures of normal or dystrophic muscles coupled to *dy* cord we have seen similar motor endplate abnormalities[4]. Such abnormal endplates were present, however, both in muscle fibres which displayed extensive cross striations and highly ordered myofilaments, and in muscle fibres which showed degenerative changes.

We tentatively conclude, therefore, that the primary lesion in muscular dystrophy is probably myogenic rather than neurogenic. Our experiments do not, however, permit us to decide with certainty between these two alternatives. The tissue culture set up may not be as well suited as originally anticipated to analyse these problems since there are strong indications that in the tissue culture environment both the penetrance and the expressivity of the dystrophic alleles are considerably diminished.

Cross bridges as the major source of compliance in contracting skeletal muscle

It has been established that the elastic properties of contracting skeletal muscle are dominated by structures within the sarcomeres We have demonstrated[1] a decrease in the instantaneous stiffness of a contracting toad sartorius at lengths greater than body length (l_0) coinciding directly with the decline in maximum isometric tetanic tension. This finding suggested that the cross bridges between actin and myosin filaments may be the major site of compliance in an active muscle, a conclusion in accordance with that reached by Huxley and Simmons[2] on the basis of a study of tension transients following rapid releases in single fibres of frog semitendinosus. Also in agreement with this conclusion is the work of Cleworth and Edmond[3] who used a light diffraction technique to demonstrate that any change in the length of the sarcomere during isometric contraction was less than 50 Å, or less than 0.1%. These studies suggest that the cross links could be the major site of elasticity within the sarcomere, but it is possible that significant compliance resides in the unbonded thin filaments, although X-ray diffraction studies of contracting muscle[4] indicate that the I-filament length does not increase by more than 0 02%. The experiments reported here were carried out to extend previous observations of muscle stiffness into the range of lengths below the resting length.

All experiments to be reported here were carried out using whole sartorii of the toad *Bufo bufo* The method used for obtaining the tension–extension curve by constant velocity releases was as described previously[1], using a release velocity of 1.4–2.5 l_0 s^{-1} (V_{max} for toad muscle was measured and found to be 1.27 l_0 s^{-1})[1].

For comparison of results from different experiments, all force values were normalised with respect to maximum tetanic force (P_0), and the changes in length were normalised with respect to body length (l_0). Plotting force against change in length produces a tension–extension curve, the linearity of a portion of which enables a linear regression

Fig. 1 Tension–extension curves from maximum tetanic tension in toad sartorius at four different lengths: ●, l_0; ▲, $0.8l_0$; ○, $0.72l_0$; ■, $0.68l_0$. The stiffness values for these curves are $77P_0/l_0$ (l_0 curve), $63P_0/l_0$ ($0.8l_0$ curve), $50P_0/l_0$ ($0.72l_0$ curve), $37P_0/l_0$ ($0.68l_0$ curve). For this muscle $l_0=25$ mm; weight$=67$ mg.
Fig. 2 Comparison of instantaneous stiffness and maximum tetanic force below body length in toad sartorii. Stiffness values (●) and tension values (○) represent the pooled data from six separate experiments. Stiffness and tension are normalised with respect to their maximum values at body length. Length is expressed as a fraction of l_0. Abscissa: sarcomere width at the corresponding length.

analysis of the points from $0.4P_0$ to P_0 and the use of the slope of the line as a measure of muscle stiffness[1].

Four tension–extension curves obtained from the same muscle at different lengths below l_0 are shown in Fig. 1. The stiffness of the contracting muscle is decreasing as the overall muscle length decreases. Furthermore, if these curves are shifted along the horizontal axis so that the point $(P_0)_l$ lies on the l_0 curve, they are not part of the same curve, indicating that the instantaneous elasticity of an active muscle as a function of load is not just determined by some passive constant element such as the tendons or the compliance of the recording equipment.

In Fig. 2, the stiffness points from six experiments are pooled and compared with the corresponding points of the tension–length relationship for the same muscles. Sarcomere widths were measured using a laser diffraction technique on whole toad sartorii.

The stiffness of the muscle remains at maximum for a short distance below the body length while the tension is falling and then, from a measured sarcomere width of about 1.82 μm, the stiffness and tension curves fall parallel to each other, with the stiffness at a given length always higher than the force. The relationship between the maximum isometric force at a given length and the stiffness at that length is shown in Fig. 3. To a first approximation, these points are linear to about $0.85P_0$ where the first sign of a decline in stiffness is observed. It was difficult to obtain values of stiffness for points below $0.2P_0$ because of the deterioration of the stimulated muscles at very short lengths[5] The stiffness–force curve may have an intercept on the stiffness axis or may fall quite sharply to zero at points below about $0.2P_0$.

A striking feature of our experiments is the similarity of our results to the relationship between metabolic activity and force at different muscle lengths in isometric tetani. Figure 3 shows the relative change in creatine phosphate hydrolysis[6], maintenance heat rate[7] and stiffness with peak tetanic tension in muscles above and below l_0. At long muscle lengths ($>l_0$) there is a very good correlation between the measured stiffness, metabolic activity and peak tetanic tension. At lengths below l_0, the stiffness is more directly related to the creatine phosphate hydrolysis and maintenance of heat rate than to isometric tension Moreover, the fact that the relative metabolic activity and normalised stiffness are consistently higher than the force suggests that there may be some internal force which opposes shortening below l_0. Such a force would naturally
Fig. 3 Relationship between metabolic activity, instantaneous stiffness and maximum tetanic tension at different muscle lengths. Closed symbols, values for lengths below l_0; open symbols, lengths above l_0. All values have been normalised with respect to their maximum value at l_0. ■, □, Maintenance heat rate; ▲, △, creatine phosphate hydrolysis; ●, ○, instantaneous stiffness. Correlation coefficient for fit of open symbols to the line through the origin and the 1, 1 point is $r=0.91$; for closed symbols $r=0.76$.

subtract from the tension produced by the myofilaments. Evidence for such a force has been provided by Gordon *et al.*[8] who have calculated an increase in internal osmotic pressure of 1 kg cm^{-2} in a muscle shortened from 40 to 75% of its initial length. Additional evidence has been provided by Simmons[9] who has shown that single fibres allowed to shorten freely in solutions of increasing tonicity exhibit a definite resistance to shortening at sarcomere lengths of 2.0 μm and between 1.92 and 1.95 μm. This corresponds to the range of sarcomere lengths over which the measured stiffness seems to be constant as the peak isometric tetanic tension declines.

In previous experiments which showed a decrease in the stiffness of contracting skeletal muscle at long lengths[1,10] it seemed possible, though perhaps unlikely, that the thin filaments in the I band might be a major source of muscle compliance. If the elastic behaviour of the active muscle were dominated by the compliance of the I band, then as the sarcomere shortens and the I-band width decreases, the overall stiffness of the muscle should increase dramatically. Our work, showing that, on the contrary, the stiffness of the contracting toad sartorius decreases as the sarcomere length is reduced and as the maximum isometric tetanic tension falls, rules out such a possibility.

Sulphydryl groups and the quinone receptor in insect olfaction and gustation

UNDERSTANDING of energy-transduction aspects of olfactory messenger–receptor interactions has been lacking[1], until the recent advances[2–6] made using the chemoreceptor protein for quinone messengers, isolated from sensory nerve membranes in the antennae of *Periplaneta americana*[7,8]. Availability of this protein for *in vitro* experiment has filled a void that existed, for several decades, between the behavioural and electrophysiological experimental capabilities in this field. With purified receptor protein available, physicochemical aspects of olfaction and gustation have become amenable to direct experiment. Here we present evidence that messenger naphthoquinones showed marked selectivity for the receptor protein when it was exposed *in vitro* to a saturating 10^{-4} M concentration of each messenger in the presence of the other Triton-solubilised proteins from the insect's antennae. The electrophoretically resolved[4,7,8] receptor-containing band only constituted approximately 13.7% of the protein in the Triton-soluble fraction, but it bound more than 75% of radiolabelled messengers. The other messenger-associated radioactivity was retained at the origin of the gels or was scattered as low level DPMs among the several other resolved bands These findings also confirm earlier experimental results[8] on the selective binding of messenger to the receptor band as resolved in 3.5% acrylamide gels.

The possible involvement of ATPases in this chemoreception by *P. americana* has been considered previously[9], and we now report that when the Triton-soluble proteins from the antennae were pre-incubated with saturating 10^{-4} M ouabain for 15 min before the addition of messenger 2-methyl-^{14}C-1,4-naphthoquinone (menadione), the amount of quinone messenger bound to the receptor was not significantly reduced from that with the control at the 0 01 level of probability Thus, active ouabain-sensitive ATPases are not involved in the primary messenger–receptor interactions in this olfactory and gustatory process.

With regard to reaction sites in the receptor, the sulphydryl reagents, N-ethyl maleimide (NEM) and iodoacetic acid (IAA), at a saturating concentration of 10^{-4} M in the Triton-soluble proteins from the antennae, showed selectivities of binding with the receptor band[4,8] in 3.5% gels that were comparable with those of the messenger naphthoquinones. The receptor-containing band was recently shown[4] to be exceptionally rich in sulphur-containing amino acids, and thus the now reported marked selectivity of the sulphydryl reagents seems reasonable. As a direct indication of the major role of sulphydryls as actual functional groups in the receptor for the messenger naphthoquinones, IAA binding to receptor was competitively reduced by preincubation of receptor with each of four naphthoquinones (Fig. 1). The order of this *in vitro* competitive binding at quinone concentrations of 5×10^{-6} to 10^{-5} M was the same as the order of the relative unchallenged binding of the four naphthoquinones to receptor, repellency or inhibition of feeding as measured in bioassays[2,10], inhibition of chemosensory neurones as

measured by electroantennograms (EAGs)[5], binding to nerve membrane-rich density gradient fractions from antennae[2], shifting of the polarographic half-wave potential ($E_{1/2}$) of the isolated receptor protein[3], and inhibition of ouabain-sensitive ATPases[9]. The completely compatible experimental results from all these levels of examining these messenger–receptor interactions support the final conclusion that sulphydryls are major reaction groups (sites) for the messenger naphthoquinones' selective binding to this receptor protein.

The receptor protein was extracted from adult male *P. americana* in the same manner as detailed previously[3,4,7,8]. The messenger naphthoquinones or sulphydryl reagents, NEM or IAA, as used as the treatment chemical in the selective binding experiments, were added to the preparation during initial tissue maceration. In the competition experiments, the ouabain was added during initial tissue maceration, or the respective messenger naphthoquinone (Fig. 1) was introduced into uniform aliquots of the receptor extract. Each extract was then incubated for 15 min before introduction of the challenger, ^{14}C-menadione or ^{14}C-labelled IAA (Fig. 1) This sequence allowed each initial treatment chemical unchallenged access to the reaction sites in the receptor protein Electrophoretic separation, the staining and quantitation of protein, the slicing of gels, and counting of radioactivity have been described[8].

Messenger naphthoquinones showed a marked selectivity of binding for the electrophoretically resolved band of Triton-soluble protein from the antennae of *P. americana* which we previously termed the quinone receptor. Sulphydryls were proven to be major reaction sites in the receptor. The fact that the primary receptor activity does not require an active ouabain-sensitive ATPase was proven by the failure of a preincubation of receptor with ouabain to alter significantly the binding of messenger naphthoquinone. This finding is compatible with our previous demonstration[9] that messenger menadione does not significantly inhibit ouabain-sensitive ATPases. Thus, any disruption of chemoreception by the ouabain-sensitive ATPase inhibiting properties of naphthoquinone messengers with a significant amount of such activity (for example, juglone, 1,4-naphthoquinone, and lawsone) is strictly attributable to effects at the non-primary levels of this sensory process.

The real test of having identified critical physicochemical

Fig. 1 Average pmol of ^{14}C-labelled IAA subsequently bound in the electrophoresed receptor-containing protein band when 10^{-4} M IAA was challenged for receptor sites by a 15 min preincubation of the receptor with increasing concentrations of each of four messenger 1,4-naphthoquinones
parameters of this chemoreception process is the use of the obtained information as the bases for predictable alteration of the sensitivity of the system in the live animal. This has been accomplished on an extensive scale, and those results are presented elsewhere[6,10].

Murine sarcoma virus pseudotypes acquire a determinant specifying N or B tropism from leukaemia virus during rescue

SEVERAL classes of murine leukaemia viruses (MuLV) are recognised according to their ability to induce XC plaque formation with high or low efficiency after infection of various mouse cell lines[1,2]. N- and B-tropic MuLVs, for example, can be distinguished on the basis of their relative ability to infect N-type or B-type mouse cells, the cells themselves differing at a single genetic locus, Fv-1 (ref. 3). Fv-1 restriction is not absolute[3], is dominant over susceptibility in F₁ hybrids[4], and may be mediated by a specific intracellular inhibitor[5,6]. Studies using vesicular stomatitis virus (VSV) pseudotypes made with N- or B-tropic MuLV have shown that Fv-1 restriction occurs after virus penetration[7,8], although the mechanism of inhibition is not known. A clear difference exists between Fv-1 restriction of MuLV and the host range restriction of avian leukaemia virus subgroups, in which host range restriction occurs at the cell surface[9,10]. Another class of MuLVs, NB-tropic, does not seem to be sensitive to Fv-1-mediated restriction[1].

Restriction of N- and B-tropic MuLVs is of interest as an example of host control of exogenous RNA tumour virus infection. Moreover, an understanding of Fv-1-mediated restriction may also shed light on the mechanism of control of endogenous viral genes which are known to exist, and are often unexpressed, in most, if not all, vertebrate cells[11].

Murine sarcoma viruses (MSVs) are a second group of murine RNA tumour viruses distinguishable from MuLV by an ability to induce sarcomas in mice and to transform a variety of cells in culture[12]. Although MSV can transform cells after solitary infection, most of the MSV isolates studied to date are termed 'defective' as they are unable to replicate unless their host cell is, in addition, productively infected with MuLV (or other 'helper' leukaemia virus)[13,14]. Certain helper-specified products seem to be required for the production of infectious MSV particles. The leukaemia virus has been shown to determine the host range[2,15] and antigenic specificity[16,17] of infectious MSV particles, which are, therefore, pseudotypes with respect to these properties. The ability of leukaemia viruses to specify properties of defective MSV has frequently been useful in determining

the function of leukaemia virus gene products. We now report that several isolates of defective MSV acquire N- and B-tropic specificities from their MuLV helper viruses.

Table 1 summarises the results of a series of focus assays using three MSV-Moloney stocks rescued from MSV-transformed BALB/3T3 non-producer cells[13] with either N-, B-, or NB-tropic MuLV. Each MSV stock, in turn, was assayed on normal BALB/3T3 cells (B type)[1,18], on a continuous line of C3H cells (N type)[4,19], and on 3T3FL cells (dually permissive)[20].

As can be seen in Table 1, MSV stocks rescued with either N-tropic or B-tropic MuLV form foci with equal efficiency in 3T3FL cells when assayed in the presence of optimal NB-tropic helper virus[20]. Also, MSV rescued with dual-tropic MuLV is equally efficient at focus formation in all three cell types.

In contrast, the stock of MSV rescued with N-tropic MuLV was almost 200 times as efficient at focus formation on N-type C3H cells as on BALB/3T3, whereas the same MSV isolate rescued with B-tropic MuLV was only 1/20 as efficient at focus formation on C3H cells (Table 1). Thus, there was nearly a 4,000-fold variation in the relative focus-forming ability of virus stocks prepared from this strain of MSV, depending on the tropism of the rescuing helper virus. (A different conclusion was reached by Yoshikura[21], possibly because the MSV focus assay procedures used did not effectively eliminate the contribution of N- or B-tropic MuLV to focus formation by rescued MSV stocks.)

The MSV assays described above and shown in Table 1 were carried out in the presence of optimal amounts of NB-tropic MuLV 'helper' virus[22]. The foci scored in these assays arise as a result of the spread of progeny MSV from transformed cells; in these conditions the possibility of interactions between MuLV 'helper' virus and N- or B-tropic MSV cannot be excluded. Replicate assay plates were therefore included without added helper virus These plates were counted 5 d after infection, and then allowed to incubate for a total of 11–13 d, at which time they were scored a second time for MSV foci. In the extended assay conditions, foci derived from MSV transformation of single cells in the absence of replicating leukaemia or sarcoma virus may be observed[23].

When the three MSV pseudotypes were tested by the longer assay procedure (Table 1), the N- and B-tropic patterns were identical to those observed above with the

same MSV stocks. MSV rescued with N-, B-, or NB-tropic MuLV exhibited the same tropism as its helper leukaemia virus. Thus, restriction of tropic MSV affects its ability to transform cells and is not altered by the presence of replicating NB-tropic MuLV in the cells used for assay. Note that restriction of N-tropic MSV by B-type cells is more pronounced than is restriction of B-tropic MSV in N-type cells, whereas the reverse pattern is observed with N- or B-tropic MuLVs[1] The restriction of B-tropic MSV in N-type cells is especially weak in assays without optimal helper virus, and, although it is a consistent finding, its significance is difficult to assess.

Foci were also counted 5 d after MSV infection in the above experiment Each of the three MSV pseudotypes showed a typical two-hit dose–response curve when assayed in permissive cells in the absence of added helper virus (data not shown)[22].

Table 1 data were obtained by titration of MSV rescued from transformed non-producer BALB/3T3 cells. A similar experiment, using dually permissive S+L- 3T3FL cells as the source of the MSV stocks, yielded nearly identical results. Therefore the Fv-1 restriction exhibited by the cell from which MSV is rescued does not seem to be a major factor in determining MSV tropism.

In addition to the Moloney isolate of MSV described above, we also tested MSV rescued from BALB/S+L cells[20], from K-BALB cells[24], and from a line of Harvey sarcoma virus-transformed 3T3FL cells recently isolated in our laboratory. All of the MSV isolates showed very nearly the same pattern of focus formation as that shown in Table 1 following rescue with N-, B- or NB-tropic MuLVs.

Our data thus show that the infectivity of MSV stocks is subject to Fv-1 restriction. MSV rescued by N- or B-tropic MuLV shows the same tropism as its helper virus, whereas dually tropic MuLV gives rise to dually tropic MSV. Cells which restrict N- or B-tropic MuLVs exhibit the same restriction to corresponding MSV pseudotypes, and the 3T3FL cell line is equally permissive to N-, B- and NB-tropic MuLV stocks as well as to their MSV derivatives (Table 1). As has been observed with N- and B-tropic MuLVs, Fv-1 restriction of MSV pseudotypes is not absolute—some MSV foci are produced in non-permissive cells.

These results indicate that MSV pseudotypes are subject to the same intracellular restriction mechanisms as are N- and B-tropic MuLVs. The tropism of the defective MSV particle is determined by its helper MuLV during the rescue

Table 1 Effect of Fv-1 restriction on the focus-forming activity of tropic MSV pseudotypes

MSV stocks were prepared following quantitative MuLV superinfection of MSV-Moloney-transformed non-producer BALB/3T3 cells. Rescue procedures were essentially as described previously[28], and virus pools were collected 11 d after superinfection. The N- and B-tropic MuLVs used for MSV rescue were filtered tissue culture supernatants of chronically infected permissive cell lines. Cloned seed stocks of these viruses were kindly provided by Dr J. Hartley of the NIH, Bethesda, Maryland. The IC clonal isolate of NB-tropic Moloney leukaemia virus[29], grown in dually permissive 3T3FL cells, was used in both the rescue experiments and as optimally diluted 'helper' virus in appropriate MSV assays. The tropism of each MuLV stock as well as the Fv-1 restriction of each cell line used was confirmed by XC plaque titration on BALB/3T3 and C3H cells[30]. Assay plates (60 mm) were seeded with 150,000 normal BALB/3T3 (B type), 80,000 C3H (N type) or 80,000 3T3FL (dually permissive) cells. All cells were treated with DEAE-dextran (20 μg ml⁻¹) before infection.
*Ratio of MSV titre in C3H cells to MSV titre in BALB/3T3 cells.
†MSV(N) = MSV rescued with N-tropic MuLV, and so on.
‡Each number represents MSV focus-forming units ml⁻¹ based on an average of two or three assay plates within the countable range. Bracketed numbers are based on foci counted 11–13 d after infection without added helper virus; numbers not in brackets are based on foci counted 5 d after infection in the presence of optimal helper virus.
§A laboratory standard pool of MSV rescued from S+L-3T3FL cells with NB-tropic MuLV was included with each assay.

process; N or B tropism is therefore a phenotypic, helper-dependent characteristic of MSV pseudotypes. Coinfection of newly infected cells with moderate amounts (m.o i.~0.1) of NB-tropic helper virus during an MSV assay does not seem to alter significantly the tropic properties of MSV pseudotypes (Table 1).

The existence of N- or B-tropic MSV pseudotypes has several implications concerning the nature of Fv-1 restriction. First, the fact that MSV acquires N or B tropism from its MuLV helper implies that the determinant present in leukaemia virus particles which specifies N or B tropism is transferable to MSV during the rescue process. Once transferred, this determinant does not become an integral part of the MSV genome. The determinant of N or B tropism may be responsible for either resistance or sensitivity to Fv-1 restriction, and NB-tropic MuLV may contribute either two determinants or none at all to its defective MSV pseudotype during rescue The factor responsible for the SV1-mediated MSV tropism is very likely distinct from the helper-derived envelope glycoprotein(s) responsible for the antigenic specificity and interspecies host range of MSV pseudotypes, as the Fv-1 restriction mechanism acts after virus penetration of resistant cells, whereas envelope glycoproteins are involved primarily in virus adsorption[25]. The determinant of MSV tropism may be analogous to the helper-dependent factor required for MSV transformation[26], found using MSV rescued by certain temperature-sensitive mutants of MuLV.

Second, MSV pseudotypes are restricted in non-permissive cells not only in their ability to replicate, but also in their ability to transform cells (Table 1) Therefore, while restriction of N- and B-tropic viruses in non-permissive cells involves the production of infectious progeny, it also extends to the expression of an MSV gene product which functions in cell transformation, and not, presumably, in leukaemia virus replication. Restriction associated with the Fv-1 locus may thus involve the simultaneous repression of several viral gene products normally produced after integration of viral information into host cell genetic material[27], or restriction may be the result of an inhibition of the integration process itself. Molecular studies with tropic MSV in permissive and non-permissive cells could distinguish between these two possibilities.

We thank Ms C. A. Kindley for assistance. These studies were supported in part by a contract from the Virus Cancer Program of the National Cancer Institute. S. G. was an NIH Visiting Fellow.

Note added in proof: The resistance of BALB/3T3 cells to transformation by MSV (N) can be abrogated by the addition of large amounts of N-tropic MuLV, but not by comparable amounts of B-tropic or NB-tropic MuLV.

Induction of erythroid leukaemia by Harvey and Kirsten sarcoma viruses

SEVERAL RNA tumour viruses including the Friend[1], Rauscher[2] and Kirsten (MLV-Ki)[3] strains cause erythroid leukaemia in mice. These agents do not transform cells *in vitro*, but provide a helper activity for the replication of defective transforming sarcoma viruses. The Kirsten sarcoma virus (KiSV)[4] was isolated from a rat inoculated with MLV-Ki, whereas the Harvey sarcoma virus (HaSV)[5] was recovered from a rat infected with the non-transforming Moloney leukaemia helper virus (MLV-M)[6]. Both sarcoma viruses contain common rat genetic sequences[7,8].

Stocks of both KiSV and HaSV cause erythroid leukaemia and solid tumours in mice[4,9,10]. The agent responsible for inducing the erythroid leukaemia has not, however, been identified. Recently, clonal KiSV- and HaSV-transformed non-producers, free of associated leukaemia virus, have been isolated *in vitro*[11–13]. We have rescued these defective sarcoma viruses with MLV-M and now show that these transforming viruses cause erythroid leukaemia in mice

Cells were maintained in Dulbecco's modified Eagle's medium containing 4.5 g l^{-1} glucose and 10% calf serum (Colorado Serum Company). The establishment of the non-transformed cell lines, NIH/3T3 (ref. 14), NRK (ref 15), and BALB/c-3T3 (ref. 16), and the isolation of HaSV- and KiSV-transformed non-producer cells[11–13] have been described. A clonal isolate of MLV-M (ref 17) was grown on NIH/3T3 cells. MLV-M was quantitated by its ability to induce syncitia formation in XC cells[18]. About 10^6 non-producer cells were transferred to a Falcon flask (area, 75 cm^2) containing 4 μg ml^{-1} polybrene (Aldrich) and infected 24 h later with 10^7 XC units MLV-M. Infected or mock-infected cells were passaged for 2 weeks. To prepare virus stock, 10^6 cells were transferred to a 75 cm^2 flask; tissue culture fluids were collected 24 h later and stored at −70 °C The *in vitro* assay for the replication of the transforming activity on NIH/3T3 cells has been described[19]. To induce erythroid leukaemia, virus stock was passed through a membrane filter (pore size, 0.45 μm) and 0 1 ml was inoculated intraperitoneally into newborn Swiss mice Three to four weeks later, the animals were killed and autopsied. Spleens were sectioned sagittally and touch preparations were made and stained with the Wright–Giemsa stain or benzidine. The spleens were then fixed[20] and the uncut surface examined for erythroblastic foci[21]. Solid tumours were identified grossly and further characterised after staining with haematoxylin and eosin[20].

MLV-M-infected HaSV- or KiSV-transformed non-producers yielded a virus that transformed NIH/3T3 and caused erythroid leukaemia (Table 1). MLV-M did not transform NIH/3T3 or cause erythroid leukaemia, nor did medium conditioned by the non-producers. Thus, the HaSV and KiSV caused erythroid leukaemia because their transforming

Table 1 Rescue of the transforming erythroid leukaemia–sarcoma viruses

Cell line	Addition of MLV-M	Replication of transforming activity	Erythroid leukaemia	Recovery of transforming virus from spleens
KiSV-NIH	No	−	−	ND
	Yes	+	+	+
KiSV-BALB	No	−	−	ND
	Yes	+	+	+
KiSV-NRK	No	−	−	ND
	Yes	+	+	+
HaSV-NIH	No	−	−	ND
	Yes	+	+	+
NIH/3T3	No	−	−	ND
	Yes	−	−*	−

One day after addition of MLV-M, the infected or mock-infected KiSV-NRK were cocultivated with 10^6 NIH/3T3 cells. Virus stocks were prepared from the medium overlaying these and other cultures as described. To assay for the recovery of transforming virus, spleens were shredded through a wire grid and a 10% cell suspension made in medium containing calf serum. The cells were removed by low speed centrifugation; the supernatant was passed through a 0.45 μm membrane filter and assayed for transforming activity on NIH/3T3 cells[19].

*Some of the mice inoculated with MLV-M developed an erythroid response, which could be noted in the spleen at 1 month of age. This response could be readily differentiated from erythroid leukaemia: the cells matured normally and the predominant nucleated erythroid cell was the orthochromic normoblast; there was no evidence of haemorrhage; and discrete foci were not evident. A similar erythroid response has been noted with the Friend helper virus[26]. Approximately 80% of these mice eventually developed the thymic tumours of Moloney leukaemia 3 months after inoculation.
ND, not determined.

activity could not be separated from their leukaemogenic activity.

A virus recovered from the spleens of the erythroid leukaemic mice transformed NIH/3T3 cells (Table 1). These transformed cells had the typical compact and piled-up appearance of KiSV- or HaSV-transformed NIH/3T3. MLV-M was also present in these spleens and was detected by the XC cell test[18].

Animals with erythroblastic leukaemia had grossly enlarged spleens with many pale, ill-defined erythroblastic foci[21]. These spleens often ruptured causing the death of the animal. More than 30% of the cells in areas of

Fig. 1 Assay of virus stock for the induction of erythroid leukaemia or sarcomas in newborn Swiss mice. Virus stock was prepared by rescuing the transforming agents from HaSV-transformed NIH/3T3 or KiSV-transformed BALB/c-3T3 with MLV-M. Both stocks had a titre of about 10^5 transforming units and 10^6 XC units ml⁻¹. Approximately 20 mice were inoculated with each dilution of 0.45 μm filtered virus stock. □, ■, HaSV (MLV-M); ○, ●, KiSV(MLV-M). □, ○, solid tumour; ■, ●, erythroid leukaemia.

erythroid leukaemia were proerythroblasts or basophilic erythroblasts, and occasional trinucleate forms were seen. There was also an increased number of more mature erythroid cells that gave a positive benzidine stain for haemoglobin. Foci of erythroid leukaemia could also often be identified in the liver.

Some of the animals inoculated with HaSV (MLV-M) or KiSV (MLV-M) also developed solid tumours. These tumours (usually rhabdomyosarcomas or fibrosarcomas) grew slowly and did not kill the host. To compare the frequency of erythroid leukaemia with that of solid tumours, animals were inoculated with serial dilutions of virus stock. At all dilutions that caused disease, the incidence of erythroid leukaemia was greater than that of solid tumours (Fig. 1). Approximately 10^2 transforming units of HaSV or KiSV caused microscopic foci of erythroid leukaemia in 50% of the inoculated animals, while 10 transforming units did not cause erythroid leukaemia. HaSV (MLV-M) and KiSV (MLV-M) caused erythroid leukaemia in Swiss, BALB/c and C57BL/6 newborn mice.

Four defective type C viruses with transforming activity for 3T3 (Abelson virus[19,21], Moloney sarcoma virus[11,22], HaSV and KiSV) have been isolated from rodents. One of these agents, the Abelson virus, causes a lymphoid leukaemia of B or null cell origin[23,24], whereas HaSV and KiSV each cause erythroid leukaemia. The transforming activity of these three defective viruses is probably responsible for affecting the growth control of haematopoietic cells to induce leukaemia. Defective transforming viruses recovered from other species may also cause leukaemia.

Transcriptional events during early phase of germination of rice embryos

GERMINATION transfers a metabolically inert embryo into an active state of growth and development. The presence of conserved mRNAs has been demonstrated in different species of eggs and seeds[1-4]. In rice embryos, germination was shown to be independent of the synthesis of RNA up to 18–24 h after the start of imbibition[5], although RNA synthesis was detected as early as 9 h after the start of imbibition. In this report, the sequence of the transcriptional events taking place during the early phase of the germination of rice embryos are presented.

Rice seeds (*Oryza sativa* L.IR-8) were germinated for different periods[5], the embryos were excised, incubated with the radioactive precursor, homogenised, and the ribosomes were separated by sucrose density gradient centrifugation[6]. The amounts of ribosomes, ^{32}P-RNA and ^{14}C-protein associated with monosomes at different stages of germination are shown in Table 1. The increase in the radioactivities of ^{14}C-amino acids and ^{32}P-orthophosphate associated with monosomes of embryos germinated for 12–24 h was reflected in the twofold increase in the amount of monosomes at 24 h. This indicated the synthesis of ribosomal components and maturation of ribosomes by 24 h of germination. The incorporation of ^{32}P-orthophosphate at 6 h was negligible, whereas it increased by sevenfold by 12 h of germination.

The ^{32}P-RNA isolated from the microsomes of embryos excised from seeds germinated for 12 and 24 h in presence of ^{32}P-orthophosphate were analysed by 2.6% polyacrylamide gel electrophoresis[7] to investigate the synthesis of rRNA (Fig. 1). Both the 12 and 24 h samples showed the two rRNA peaks (I and II) indicating synthesis. These results imply that the rRNAs were synthesised in the early phase (0–12 h) and were retained during the entire experimental period (24 h). No significant incorporation of ^{32}P-orthophosphate into microsomes could be detected,

Fig. 1 Analysis of ^{32}P-RNA from microsomes by SDS-polyacrylamide gel extrophoresis. ^{32}P-RNA isolated from microsomal fraction of embryos excised from seeds grown in ^{32}P-orthophosphate for 12 (●) or 24 h (■) was dissolved in electrophoresis buffer (40 mM Tris, 20 mM sodium acetate, 2 mM EDTA, and 0.2% SDS adjusted to pH 7.8) and 0.1 ml (46,000 c.p m.) was applied on to 2 6% gel and subjected to electrophoresis at 5 mA per tube for 75 min. The gel was dried between filter paper folds, cut into 1 mm thick strips with the paper and counted. ^{14}C-labelled RNA from *Escherichia coli* was used as standard.
Table 1 Quantity of ribosomes, ^{32}P-RNA and ^{14}C-protein at different stages of germination

Germination (h)	Ribosome (A_{260})	c.p.m. ^{32}P-RNA	c.p.m. ^{14}C-Protein
6	0.30	1,800	9,200
12	0.36	12,500	10,900
24	0.63	44,200	—

Embryos (100) at different stages of germination were homogenised in 3.5 ml 25 mM Tris HCl, pH 7.4, 10 mM MgCl₂, 5 mM β-mercaptoethanol and 0.25 M sucrose with sand in a mortar at 4 °C, centrifuged at 2,500g for 5 min; the supernatant fraction was further centrifuged at 12,000g for 15 min. Supernatant fraction (1 ml) was layered on 27.2 ml 15–30% sucrose gradient and spun at 25,000 r.p.m. in a SW-25.1 rotor for 3 h at 4 °C. Tubes were punctured and fractions of 50 drops were collected. Quantity of ribosomes was estimated by absorbance at 260 nm. For incorporation studies, the embryos were incubated in 2.5 ml 0.1 M Tris-HCl pH 7.8, 1% glucose and 50 μg ml⁻¹ chloramphenicol in presence of ^{32}P-orthophosphate (60 μCi) or ^{14}C-algal protein hydrolysate (10 μCi) at 30 °C for 2 h and the ribosomes were separated as before. Each fraction was made 10% with respect to TCA and the precipitate was washed free of lipids on glass fibre filters and counted[5]. Radioactivity under monosome peak represented ^{32}P-labelled RNAs or ^{14}C-labelled proteins associated with ribosomes.

however, when the seeds were germinated for 6 h in presence of ^{32}P-orthophosphate. This observation and the data presented in the Table 1 indicate that rRNA appears in the cytoplasm between 6 and 12 h of germination. In wheat embryos the mature ribosomes have been detected only after 6 h of germination[8].

Although the 24 h labelled ^{32}P-RNA isolated from microsomes also includes the RNA synthesised up to 12 h, there are differences in the two patterns (Fig. 1). Some new peaks of radioactivity (<16S) did appear by 24 h of germination, indicating the synthesis of a new species of RNA.

The base compositions of ^{32}P-RNAs isolated from embryos labelled for 1 h at 12, 18 and 24 h of germination are given in Table 2. The G+C/A+U ratio of 1.39 of the pulse-labelled RNA at 12 h of germination indicated the predominant synthesis of rRNA during 0–12 h. RNAs synthesised during the later periods have G+C/A+U ratios less than one, indicating their DNA-like nature. The synthesis of RNAs rich in G+U has been reported during the germination of wheat embryos[9]. The base composition of the pulse-labelled RNAs in rice was identical with the conserved mRNA in embryos[4] of wheat seeds and RNAs synthesised during germination[9]. rRNAs are synthesised in rice embryos before the synthesis of mRNA and may have a role in the transport of the mRNAs from the nucleus to cytoplasm[10,11]. The synthesis of mRNA itself takes place after the first cycle of DNA synthesis, the latter being maximum at 12–18 h (unpublished). Analysis of the postmicrosomal supernatant ^{32}P-RNA on 10% sodium dodecyl sulphate (SDS)–polyacrylamide gel showed the incorpora-

Table 2 Base composition of pulse-labelled RNAs at different stages of germination

Germination (h)	% Total GMP	UMP	AMP	CMP	G+C / A+U
12	35 0	21.5	21.1	21.2	1.39
18	25.3	26.7	25.3	22.5	0.94
24	29.9	33.8	18.9	17.9	0.91

Embryos (500) at different stages of germination were labelled for 1 h with ^{32}P-orthophosphate (160 μCi) in 3.5 ml incubation medium (Table 1), homogenised in 6 ml 10 mM Tris-HCl, pH 7.8, 20 mM KCl and 10 mM MgCl₂ and 0.1 M Na₂HPO₄ Homogenate was centrifuged at 1,500g for 10 min and ^{32}P-RNA was isolated from the supernatant fraction[8]. RNA was hydrolysed and the nucleotides were separated by electrophoresis on Whatman no. 1 paper at 2,000V for 105 min in pyridine acetate buffer, pH 3.5, according to the method of Sebrings[12]. Nucleotides were identified by using internal standards and quantitated by the amounts of radioactivity.
Fig. 2 Analysis of ^{32}P-RNA from postmicrosomal supernatant fraction by SDS-polyacrylamide gel electrophoresis. ^{32}P-RNA from postmicrosomal fraction (■, 6 h; ●, 12 h) was isolated, dissolved in electrophoresis buffer (Fig. 1) and 0.1 ml (2,400 c.p.m.) was applied on 10% gel and subjected to electrophoresis at 5 mA per tube for 3.5 h. Gels were cut into 2 mm thick slices, dried on filter paper disks and counted. ^{35}S-labelled tRNA from *Pseudomonas aeroginosa* was used as standard.

tion of ^{32}P-orthophosphate into 4S RNA as early as 6 h of germination (Fig. 2). This may either represent the synthesis and/or the turnover of CCA ends of tRNAs.

From the data presented above and from the published results[5], commencement of the synthesis of various macromolecules during the early phase of the germination of rice embryos are represented as:

Protein	tRNA	rRNA DNA	mRNA Maturation of ribosome

0————0.5————6————12————24

Time of germination (h)
This scheme is at variance with that reported by Dobrzanska *et al.*[9], in which the mRNA synthesis takes place from the beginning of the germination of wheat embryos after presoaking the seeds for 8 h at 2 °C. When wheat seeds were germinated without presoaking, however, synthesis of rRNAs was found to be the earliest transcriptional event[8].

Polyribosome formation in early wheat embryo germination independent of either transcription or polyadenylation

EARLY germination of seed embryos is characterised by a rapid increase in polyribosome content and rate of protein synthesis[1,2], and there is evidence[3-8] that these events are a consequence of the mobilisation of preformed messenger RNA[9]. We observed that new mRNA synthesis could be measured at this time of rapid polyribosome formation[10]. Using cordycepin and α-amanitin, inhibitors of this mRNA synthesis, we have now confirmed that preformed mRNA has an important role in early germination, and have found

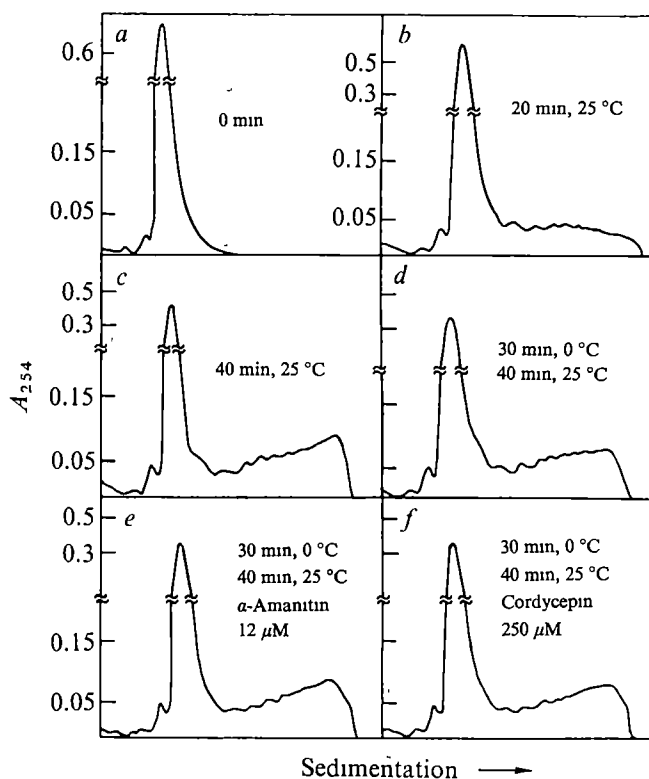
Sedimentation ⟶


Fig. 1 Polyribosome formation during early germination of wheat embryos and the effect of RNA Inhibitors. Embryos (125 mg) imbibed in 1.6 ml water either directly at 25 °C (*a*, 0 min; *b*, 20 min; *c*, 40 min) or at 1 °C for 30 min followed by 40 min at 25 °C (*d*, control; *e*, 12 µM α-amanitin, *f*, 250 µM cordycepin) were frozen in dry ice. After grinding with a mortar and pestle cooled in dry ice, the "dry ice powder" of the cells was homogenised in a Duall glass homogeniser with 7 ml of isolation media (0.25 M sucrose, 20 mM KCl, 2 mM MgCl₂, 40 mM Tris-HCl pH 7.6, 5 mM mercaptoethanol), cleared by centrifugation (23,000g for 10 min), layered over 2 ml of a cushion of 1.8 M sucrose, 20 mM KCl, 2 mM MgCl₂, 40 mM Tris-HCl pH 7.6, 5 mM mercaptoethanol, and centrifuged for 60 min at 150,000g in a Spinco Ti 50 rotor. (The isolation through the cushion removes some of the monosomes from the ribosome pellet[11] Nevertheless, it is particularly useful both in excluding ribonucleoprotein particles of non-polysomal origin and in increasing the accuracy of the analysis of the change in polyribosome content.) The resulting pellet was suspended in 0.8 ml of 20 mM KCl, 1 mM MgCl₂, 40 mM Tris-HCl pH 7.6, 1 mM dithiothreitol and clarified by centrifugation for 10 min at 23,000g. A volume containing 150 µg RNA was layered on a 15–38% linear sucrose gradient over a 1 5 M sucrose cushion (both gradient and cushion solutions contained 20 mM KCl, 5 mM MgCl₂, 50 mM Tris-HCl pH 7.6, 1 mM dithiothreitol) and centrifuged for 45 min at 230,000g in a SW50 1 rotor. The gradients were fractionated using a modified ISCO density gradient fractionator with continual monitoring of absorbance at 254 nm. The prominent peak of absorbance is that of 80S ribosomes The polyribosome content of the six preparations shown are 3, 22, 55, 46, 42, and 44%, respectively.

Table 1 Effect of cordycepin and α-amanitin on uridine incorporation into RNA of ribosomes during rapid polyribosome formation

Uptake × 10⁸ (c.p m. per 250 mg embryo)	Acid-insoluble radioactivity (c.p.m./mg RNA)	Inhibition (%)
2.6	6,592	
+cordycepin (250 µM)	3.2	1,736	73
+ α-amanitin (12 µM)	2.7	471	93

Embryos (125 mg) preimbibed either water, cordycepin (250 µM) or α-amanitin (12 µM) for 30 min at 0 °C and were then transferred to a similar solution containing either water or the inhibitors, and ³H-uridine (150 µCi) for 40 min at 25 °C. Two batches of embryos were combined; ribosomes were isolated as in Fig. 1; RNA was extracted as in Table 3, and the acid-insoluble radioactivity was determined.

that polyribosome formation at this time is independent of both transcription and of polyadenylation.

Figure 1a-c shows a time course of polyribosome formation in wheat embryos exposed to water at 25 °C. At 20 min considerable mRNA was found in polyribosomes, and by 40 min polyribosomes of maximal size predominated. With some preparations there was no further increase in poly-

tial inhibition of the ultimate increase in protein synthetic capacity. Nevertheless, the time course of polyribosome formation (Fig. 1d) was identical to that at 25 °C. In the presence of either cordycepin (250 µM) or α-amanitin (12 µM), polyribosome formation was unaffected (Fig. 1e and f) Table 1 shows that RNA synthesis during the period of rapid polyribosome formation was inhibited about 70% by cordycepin and more than 90% by α-amanitin. Thus early polyribosome formation is essentially independent of RNA synthesis.

The effectiveness of the inhibitors made possible a test of the involvement of polyadenylation in the recruitment of preformed mRNA, an idea first suggested for the fertilised sea urchin egg[12,13], and recently advanced in studies of enzyme formation in germinating cotton seed cotyledons[14]. We compared the relative incorporation of ³H-uridine and ¹⁴C-adenosine in the presence and absence of the inhibitors. Both these precursors can be expected to label the internal transcribed component of the mRNA, while only adenosine labels the poly(A) tract at the 3′ terminus. If polyadenylation of preformed mRNA were a prerequisite for polyribosome formation, it would not be inhibited by cordycepin or α-amanitin (as neither affects polyribosome formation, Fig. 1), and the process would be revealed by a substantial retention of adenosine incorporation, particularly in relation to that of uridine.*

In practice, the labelled RNA was fractionated into

Table 2 Relative inhibition by cordycepin and α-amanitin of uridine and adenosine incorporation into mRNA

	³H-Uridine		¹⁴C-Adenosine	
	Acid-insoluble Radioactivity (c.p.m./mg RNA)	Inhibition	Acid-insoluble Radioactivity (c.p.m /mg RNA)	Inhibition
poly(A)−	1,263	—	934	—
+ cordycepin (250 µM)	635	50%	657	30%
+ α amanitin (12 µM)	280	78%	245	74%
poly(A)+	3,435	—	2,615	—
+ cordycepin (250 µM)	592	83%	480	82%
+ α amanitin (12 µM)	131	96%	194	93%

Embryos imbibed and were incubated as in Table 1 except that the incubation medium contained ³H-uridine (150 µCi) and ¹⁴C-adenosine (15 µCi). The RNA extracted from the ribosomes was fractionated on oligo(dT)–cellulose columns[16] into non-adsorbing (poly(A)−) and adsorbing (poly(A)+) components. Each fraction was precipitated with 5% trichloroacetic acid, collected on glass fibre filters and counted.

ribosome content for up to 5 h of germination whereas with other preparations we found increases of up to 15% In preliminary trials with inhibitors, we found that RNA synthesis could be inhibited maximally if the embryos had imbibed the inhibitors at 0 °C. In these conditions (30 min at 0 °C) no polyribosomes were formed. Furthermore, no RNA was synthesised during this period. Preimbibition in the cold caused some diminution of polyribosome formation during subsequent exposure to 25 °C (compare percentage polyribosomes of Fig. 1c and d), as well as a par-

poly(A)− and poly(A)+RNA, the latter providing an enrichment of radioactivity incorporated into mRNA. The data obtained (Table 2) show that the presence of the inhibitors, both of which effectively suppress incorporation into mRNA, does not cause a difference in the relative incorporation of the two precursors. We therefore conclude either that there is no significant polyadenylation of the preformed mRNA, or that the inhibitors are as effective in suppressing poly(A) synthesis as they are in preventing transcription The latter alternative would allow polyadeny-

*This expectation is valid only if the amount of preformed mRNA entering the polyribosomes is at least of the same order of magnitude as that synthesised in the period of analysis. The RNA content of polysomes after 40 min, as determined from changes in absorbance (Fig. 1), is 100 µg per 125 mg of embryo. Based on an average molecular weight of 6 × 10⁵ for mRNA and an mRNA concentration of 2% in polyribosomal RNA, this represents a net increase of 3.3 pmol of mRNA The adenosine incorporation into mRNA (Table 2) was 750 c p m per 125 mg embryo. The uptake of 1 × 10⁶ c p m. ¹⁴C-adenosine into the trichloroacetic acid soluble pool (data from the experiment of Table 2). and the ATP content of 150 nmol (ref. 15 and unpublished observations of Cheung. C. P), both per 125 mg of embryo, together with unpublished observations (Obendorf,

R. A.) showing that within 30 min of exposure, 45% of radioactive adenosine taken up by embryos is in ATP, enable the determination of the specific activity of the pool ATP as 3 c p m. pmol⁻¹. Again, based on a molecular weight of 6 × 10⁵ for mRNA and a tract of 100 adenosine residues (molecular weight 30,000) at the 3′ terminus, we have a total of 575 pmol adenosine per pmol of mRNA. The incorporation data calculate to 250 nmol of adenosine incorporated or a net synthesis of 0.4 pmol of mRNA. This value per se suggests that new synthesis could not account for the mRNA mobilised into polyribosomes. It clearly establishes that polyadenylation of preformed mRNA (in the presence of the inhibitors) would be easily detected, if it occurred.

Table 3 Poly(A) content of dry and imbibed wheat embryos

	³H-poly(U) hybridised (ng)	
μg RNA	Dry	Imbibed
6	4	4
11	13	9
28	32	24
55	45	46

Samples of dry and 40-min imbibed embryos (125 mg) were converted into dry ice powders. The powder was suspended in 3 0 ml of extraction solution (0.1 M sodium acetate, 0.1 M NaCl, 50 mM Tris-HCl, pH 8.2, 10 mM EDTA, pH 7 2), made to 0.5% with SDS and mixed with 5 ml of phenol-chloroform (1 : 1, v/v)[17]. The mixture was homogenised for 2 min in a Teflon motor driven homogeniser and centrifuged at 23,000g for 10 min. The aqueous phase was removed and kept on ice, while the phenol phase and the interphase were re-extracted with 3.0 ml of extraction solution at 50 °C After centrifugation, the aqueous phase and the interphase were combined with the previous aqueous phase, and re-extracted with 5 ml of phenol-chloroform for 10 min on a rotary shaker at room temperature. After centrifugation, the interphase was discarded and the aqueous phase was extracted again with 5 ml of phenol-chloroform. The aqueous phase was then mixed with 2 volumes of ethanol and kept overnight at −20 °C. The precipitate was washed twice with 3.0 ml of 3.3 M sodium acetate, pH 6 0 (ref. 18), once with 70% ethanol, 0.1 M potassium acetate, vacuum dried and dissolved in 50 mM potassium acetate, 10 mM Tris-HCl, pH 7.6. Aliquots, as indicated, were taken for determination of ³H-poly(U) hybridisation[19]. The yields of total RNA were 2.5 mg per sample and were similar for both the dry and imbibed samples. The data for poly(U) hybridisation are corrected for a background of 1 ng (22 c p m.) hybridised in the absence of exogenous RNA.

lation of preformed mRNA to occur in early germination but it would not be obligatory to the recruitment of the preformed mRNA. In either event, polyadenylation is clearly not a prerequisite for polyribosome formation. Finally, as a direct test for the occurrence of polyadenylation, we have analysed total RNA of both dry embryos and those that had imbibed for 40 min Table 3 shows that the capacity of the RNAs to hybridise ³H-poly(U) were quite similar. Since the RNA content of both types of embryo was comparable (see legend to Table 3) we conclude that the poly(A) content of embryos either dry or after imbibition is similar, and that the quantity of newly synthesised poly(A)-containing mRNA is negligible in comparison with that pre-existent in the embryo. The mechanism by which the preformed mRNA is recruited into the translational system remains to be investigated.

We thank Dr. T. Wieland for α-amanitin. This research was supported by grants from the US Public Health service, the NIH, and the NSF; and by an appropriation from the Commonwealth of Pennsylvania

Fluoride concentrations in developing enamel

THERE is at present great interest in the effects of fluoride on the skeletal and dental tissues, owing to its considerable beneficial effect on dental health[1], its potential use in the treatment of bone disease[2,3] and, somewhat paradoxically, its capacity to cause dental and skeletal fluorosis[4,5]

The effect of fluoride on teeth has been well documented and particular attention has been paid to its distribution in dental enamel The relatively high concentration of fluoride in the enamel surface[6,7] has been regarded by many as a protective barrier against carious attack. Considerable amounts of fluoride are present in the enamel before the tooth erupts into the mouth[8] and are probably acquired during the period of tooth development when, as indicated by ^{18}F studies[9,10], fluoride ions are rapidly incorporated by the mineralising tissue. Fluoride exerts its effect on the caries susceptibility of the teeth[11] particularly during this period and it is only during the period of development that fluoride can bring about the changes associated with dental fluorosis[12]. In spite of the obvious concern with this period of development, because of technical difficulties with microsampling and analysis, little or nothing is known about the concentrations of fluoride in developing enamel or in any other calcified tissue during its period of mineralisation.

Using recently developed micro-analytical techniques[13] we therefore attempted to determine the pattern of fluoride distribution in the developing enamel of the continuously growing rat incisor; this was chosen because all stages of mineralisation can be seen in a single tooth A preliminary study[14] indicated that in normal animals the concentration of fluoride in the forming enamel decreased as the tissue matured This was somewhat surprising in view of the many statements in the literature that fluoride concentrations in mineralised bone, dentine and enamel tend to increase with time[15-17].

Subsequent work has confirmed our preliminary finding. Wistar rats reared on a stock diet (Oxoid rat cake, fluoride concentration 10–14 p p.m. per dry weight) were killed at about 250 g body weight, the lower incisors removed and a series of about 20 enamel particles weighing 10–100 μg dissected from each tooth. These particles of enamel formed a series representing the different stages of development from partially mineralised tissue near to the root apex to the highly mineralised enamel of the maturing region (Fig 1)[18]. Each enamel specimen was ashed and analysed for fluoride, using the Orion electrode[19], and for phosphorus, using the method of Chen, Toribara and Warner[20] Figure 2 shows the variations in fluoride con-

Fig. 1 Diagram of rat incisor, indicating different stages of enamel development and regions from which enamel samples were taken
Fig. 2 Distribution of fluoride and phosphorus along the developing enamel of the continuously growing rat incisor (dry weight). The part of the tooth shown and analysed corresponds to the developing part of the root as indicated on the left-hand side of Fig. 1.

centrations and phosphorus concentrations in the developing rat enamel per dry weight tissue. The fluoride concentration was higher in partially mineralised than in the more highly mineralised maturing enamel. The concentration in the partially mineralised enamel was not constant, however. At or just before the stage of development in which the enamel began to mineralise rapidly, fluoride concentrations were particularly high. The concentration fell rapidly as the mineral content of the tissue approached that of mature enamel.

Since information about teeth of limited growth would be more directly relevant to the situation in the human dentition, we carried out similar determinations on enamel dissected from the developing incisors of bovine foetuses. The pattern of fluoride distribution along the enamel of each individual tooth was considerably different from that of the rat incisor This was to be expected, since the enamel of each bovine tooth was at a different stage of development, depending on foetal age, and no single tooth exhibited the full spectrum of mineralisation equivalent to that of the rat incisor A more complete developmental series must be examined before the full picture emerges but it seems from the teeth illustrated by Fig. 3a–d that, again, the fluoride content of the fully mineralised enamel is lower than that of the partially mineralised tissue.

Independently, R. L. Speirs has now also reported unpublished findings that the fluoride content of developing enamel from pig teeth decreases as the density of the enamel increases

There are several possible explanations for this decrease in fluoride concentration. The first is that fluoride, perhaps acquired by ionic exchange when the enamel is only partially mineralised, might be diluted by the subsequent deposition of relatively fluoride-free enamel. This is

suggested by the rat data in Fig. 2. A similar suggestion was made by Gedalia, Garti and Epstein[21] to explain an observed decrease in the fluoride concentration of developing human teeth between the eighth and ninth months of foetal life. The observed increase in mineral content of the foetal teeth, however, was insufficient to account fully for the decrease in fluoride concentration. In the bovine teeth (Fig. 3) a comparison between the decrease in fluoride concentrations and the concomitant variations in phosphorus content leads also to the conclusion that, here, dilution could not alone explain the fall in fluoride concentration.

Ruzicka and Mrklas (personal communication) suggested that since the fluoride concentration of the skeleton would increase with age, more skeletal fluoride would be released during the normal processes of bone remodelling and the fluoride concentration of the blood would gradually rise with age. This would in turn be reflected in the fluoride concentration of the most recently formed enamel, towards the root apex. Since Ruzicka and Mrklas made this interesting suggestion, it has been shown that the concentration of fluoride in blood does indeed reflect that in the skeleton[22]. Whether this could entirely account for such elevated fluoride concentrations in forming enamel, however, seems doubtful, for the change in the fluoride content of the skeleton over the period of incisor formation would be relatively small, and it would not alone explain the peak concentration of fluoride in the rat incisor just before the final phase of mineralisation; this peak will be mentioned later.
Fig. 3 Distribution of fluoride and phosphorus along the developing enamel of four deciduous bovine incisors taken from foetal calves aged; a, 6.0; b, 6.8; c, 7.8; and d, 8.7 month (dry weight).

The final possibility, and one which seems to have the greatest experimental support at present, is that some of the fluoride acquired during the early stages of enamel development is lost as the tissue mineralises. The ^{18}F studies of Wallace-Durbin[9] showed that the ^{18}F activity of bones and teeth from rats injected with the isotope reached a maximum value and then decreased with time, suggesting that at least some of the fluoride acquired by the mineralising tissue may be lost again. A preliminary attempt by ourselves to relate the fluoride content of the enamel to the volume of the particles dissected from the rat incisor (a procedure intended to eliminate the possibility that the fluoride concentrations fell as a result merely of dilution by the increasing weight of mineral) also supported the view that some of the fluoride acquired during the earlier stages of development is lost as the tissue matures[23].

The recent unpublished findings of Speirs similarly point to fluoride loss.

Although the partially mineralised enamel of the rat incisor had, overall, a higher fluoride concentration than the maturing tissue, there was within this region a fairly consistent pattern of fluoride distribution. A peak of relatively high fluoride concentration usually occurred just before the phase of rapid mineralisation, that is, at or before the boundary between the translucent and opaque enamel, indicated by a V in Fig. 2. The position of this site seems to correspond to a region where ^{32}P-labelled phosphate is preferentially taken up both *in vivo* and *in vitro*[18]. The high ^{32}P activity found in this region seemed to reflect the physicochemical state of the enamel and perhaps fluoride, like phosphate, is incorporated into forming enamel mainly by diffusion into relatively perm-eable tissue. We have no information about the nature of fluoride binding in this highly hydrated region of tissue. The implication in the literature that fluoride is largely bound to the mineral part of enamel is almost certainly justified in the case of mature enamel but is perhaps not without question in this partially mineralised tissue. It seems possible that some of the fluoride might be free, or bound to the organic matrix, as suggested previously by Hammarström[10], and perhaps subsequently lost as part of the matrix is withdrawn from the enamel during mineralisation.

Growth-dependent changes in terminal heterogeneity involving 3'-adenylate of bacterial 16S ribosomal RNA

THE 3' terminus of the 16S RNA from the small subunit of bacterial ribosomes is directly involved in ribosomal function[1-3]. On the basis of 3'-terminal sequence analysis of bacterial rRNAs, we have proposed that a short sequence of nucleotides in this region has a direct base-pairing role in both the initiation and termination of protein synthesis[4,5].
Fig 1. Growth-dependent changes in proportion of *Ps. aeruginosa* 16S rRNA molecules containing a 3'-terminal adenosine residue. *Ps. aeruginosa* was grown in L broth (1% bactotryptone, 0.2% yeast extract, 0.5% glucose, 0.5% NaCl)[8] at 37 °C with vigorous shaking. Samples were taken at intervals, the A_{540} determined, the RNA extracted[9] and the individual rRNA species labelled with ^{3}H-isoniazid[7,9]. The proportion of 16S rRNA molecules terminating in either adenosine or uridine was determined by paper electrophoresis of the labelled nucleoside hydrazones released by pancreatic RNase digestion[4,7]. ●, A_{540}; ○, ratio of c.p.m in adenosine-isoniazid hydrazone to c.p.m. in uridine-isoniazid hydrazone.

This hypothesis is based on two sets of observations. First, the degree of complementarity between the ribosome binding sites of coliphage mRNAs and the pyrimidine-rich 3' sequence of a number of bacterial 16S rRNAs reflects the cistron selectivity of the ribosome[6]. Second, the 3'-terminal trinucleotide of *Escherichia coli* 16S rRNA (UUA$_{OH}$) is the only trinucleotide able to recognise, by standard base pairing, all three nonsense triplets; the strengths of the proposed pairing interactions correlate with the different degrees of suppressibility of the three nonsense codons in suppressing strains of *E. coli*[4]. A similar role has previously been proposed for the highly conserved 3' terminus of eukaryotic 18S rRNA which also terminates in UUA$_{OH}$ (refs 6 and 7).

3'-sequence analysis of rRNA from bacteria other than *E. coli* shows that the 16S rRNA of several species also terminates in UUA$_{OH}$ (ref. 5). 16S rRNA from one member of this group, *Pseudomonas aeruginosa*, however, has a large proportion of molecules which lack the 3'-terminal adenylic acid and two 3' sequences, CUCUCCUUA$_{OH}$ and CUCUCCUU$_{OH}$, are found in approximately equal proportions; no such heterogeneity is found at the 3' termini of 23S rRNA from any bacteria examined (ref. 5 and J. S., unpublished).

As the proportion of 16S rRNA molecules lacking the 3'-terminal adenylic acid varied between different preparations of *Ps. aeruginosa* RNA, we have investigated the influence of bacterial growth conditions on 3'-terminal heterogeneity. In this report we show that the level of 3'-terminal adenylation of *Ps. aeruginosa* 16S rRNA is a function of bacterial growth rate.

Ps. aeruginosa, adapted to L broth[8], was grown at 37 °C with vigorous shaking. Samples were removed at intervals, the cells collected by centrifugation and immediately extracted with phenol-cresol-aminosalicylate[9]. rRNAs (16S and 23S) were separated on sucrose gradients; in all instances the A_{260} ratio of 23S:16S RNA was 2:1. The 3' termini were labelled with ^{3}H-isoniazid and the RNA digested with pancreatic ribonuclease[4,7]. The relative amounts of 3'-terminal adenosine and 3'-terminal uridine in 16S rRNA were determined by paper electrophoresis of the labelled digest[4,7]. The

3'-terminal nucleosides of 23S rRNA were determined by the same method.

Figure 1 shows the proportion of 16S rRNA molecules containing 3'-terminal adenosine, plotted as a function of cell density. The 3'-terminal sequences of the 16S rRNA are initially UUA_{OH} and UU_{OH} in the ratio 0.6:1. By 1 h after inoculation, this ratio had increased to 2.8:1, continued to increase during exponential growth and peaked at approximately 4.5:1 in late logarithmic phase. As the cell growth rate slows the ratio rapidly declines to 1.5:1 in early stationary phase; the rapidity of this change suggests that 3'-adenylate residues are removed from pre-existing 16S rRNA molecules during this period. This ratio falls to 0.6:1 after overnight growth. No significant 3'-terminal heterogeneity was found in 23S rRNA isolated from the same samples; at all stages of the growth curve at least 90% of the 23S molecules terminated in $PyCA_{OH}$.

These results suggest that single adenylate residues may be added post-transcriptionally to the 3' terminus of 16S rRNA *in situ*. Terminal heterogeneity involving adenylic acid has also been observed at the 3' terminus of bacteriophage T7 mRNAs cleaved from a large precursor RNA *in vivo*[10]. The same RNA species, when produced by specific *in vitro* cleavage of the T7 precursor RNA with RNaseIII, contain no detectable 3'-terminal adenosine, suggesting that the 3'-adenylate residues are added post-transcriptionally[11]. Note that these T7 mRNAs also contain a 3'-terminal pyrimidine-rich sequence as is found in 16S rRNA (refs 5, 10 and 11). With T7 mRNAs, the terminal addition of adenylic acid seems to be less specifically regulated than that reported here for 16S rRNA, as between one and three adenylate residues are added to the 3' terminus of the RNA (ref. 10).

In the light of these results, it is of interest that a number of bacteria (including *E. coli* and *Pseudomonas*) and also yeast, contain a ribosome-bound ATP–RNA adenyltransferase[12-17]. *In vitro* this enzyme catalyses the 3'-terminal addition of adenylate residues to RNA and, at least for *Pseudomonas*, demonstrates a preference for the 3' end of rRNA, particularly 16S rRNA, over that of tRNA or homopolyribonucleotides[16]. In yeast, the amount of ribosome-bound enzyme decreases towards late log phase[17].

We have also found substantial 3'-terminal heterogeneity in *Bacillus stearothermophilus* 16S rRNA (ref. 5) and low level heterogeneity at the 3' end of both *B. subtilis* and *Caulobacter crescentus* 16S rRNA. A small proportion ($\sim$12%) of *E. coli* 16S rRNA molecules (which normally terminate in UUA_{OH}) lack a 3'-terminal adenosine when isolated from early stationary phase cells or after a nutritional 'shift-down' (J. S., unpublished). There are previous reports of 3'-terminal heterogeneity in *E. coli* 16S rRNA (ref. 18).

The results presented here may reflect growth-dependent changes in the level or localisation of an enzyme responsible for the addition of 3'-terminal adenylate. Alternatively, changes in the degree of heterogeneity could arise from alterations in accessibility to adenylating enzymes of the 3' terminus of 16S rRNA in different functional states of the ribosome. In view of the suggestion that the 3' trinucleotide may recognise intercistronic nonsense triplets and terminator codons on mRNA (ref. 4), however, a direct regulatory role for the 3'-adenosine in converting UU_{OH} to UUA_{OH} (*E. coli, Ps. aeruginosa*), and CU_{OH} to CUA_{OH} (*B. stearothermophilus, C. crescentus*) should also be considered. Further studies on the functional activity of ribosomes containing 16S rRNA lacking a 3'-adenylate should resolve these questions.

Differences in transcription of unique DNA sequences between neuronal and glial cells

OUR previous report[1] provided evidence for the existence of the brain-specific nuclear RNA using the RNA–DNA hybridisation method. As the neuronal and glial cells in the brain possess specific compositions and functions, each of these cells probably contains cell-specific RNA, as suggested by Church and Brown[2]. In fact, Hydén *et al.*[3] found remarkable differences in base composition between the total RNA of neuronal and glial cells. This difference may be accounted for by a greater proportion of cytoplasmic (ribosomal) RNA present in the neurone[4]. This report provides new evidence for the existence of cell-specific RNA in brain, using a unique DNA–³H-RNA hybridisation method.

Fifty minutes after injection of 5,6-³H-uridine (specific activity 43 Ci mmol⁻¹, Radiochemical Centre, Amersham) into the subarachroidal space of a 15–18-d-old rat, the animal was decapitated. Then the brain was removed and homogenised in a solution containing 2.2 M sucrose and 1.5 mM $CaCl_2$, and the homogenate was centrifuged for 60 min at 70,000g. The precipitated nuclei were gently homogenised in 2.0 M sucrose containing 1.5 mM $CaCl_2$ and layered over a discontinuous gradient of 2.2, 2.35, 2.4 and 2.55 M sucrose. The rotor (Hitachi RPS 25-2) was spun for 120 min at 75,000g. The L fraction, recovered at the interface between 2.2 and 2.35 M sucrose, mainly contained neuronal nuclei; and the S fraction, obtained at the bottom, consisted of oligodendroglial nuclei. RNA was extracted from each cell nucleus with a SDS–hot phenol–bentonite procedure[5] and treated with DNase (electrophoretically pure, Worthington, USA) and with Pronase, and finally passed through a Sephadex G50 column. Unlabelled RNA was extracted from the neuronal and glial nuclear fractions by a similar procedure. DNA was isolated from rat brain nuclei by using a modification of Marmur's method[6]. For RNA–DNA hybridisation with a DNA excess, DNA was sonicated to a molecular weight of about 170,000, as estimated by the method of Studier[7], then precipitated with ethanol and further purified by filtration through Sephadex SP50.

To examine transcription in brain cells, two procedures were used: first, RNA–DNA hybridisation, using a membrane filter in the presence of formamide, and immobilisation of DNA on membrane filters (Millipore HAWP)[8]; and second, RNA–DNA hybridisation with excess DNA in solution[9,10]. Figure 1a shows the results obtained with the membrane filter hybridisation technique. When the rapidly labelled RNA of the S fraction was competed with each unlabelled RNA of L and S fractions, almost identical competition curves were obtained with either RNA of the L or S fraction. In the case of labelled RNA of the L frac-
Fig. 1 Competition by unlabelled RNA from L fraction (○) and S fraction (●) in the hybridisation of ³H-labelled RNA from S fraction with brain DNA. *a*, RNA–DNA hybridisation was carried out at 35 °C for 25 h in glass vials in 2 ml 6-SSC–formamide (1:1 v/v). Each incubation medium contained 25 µg ³H-labelled RNA from S fraction (280 c.p.m. µg⁻¹), DNA filter (10 µg) and various amounts of unlabelled competitor RNA. Then the hybrid-containing membrane filters were incubated with RNase and washed on each side. Finally the filters were dried and counted in a scintillation counter. The radioactivity bound to DNA without competitor was 200 c.p.m. and is taken as 100%. *b*, Hybridisation with a DNA excess was carried out by a modified method of Melli *et al.*[9]. DNA fragments in 0.03 M phosphate-buffered saline (PBS) were heated at 100 °C for 10 min. ³H-labelled RNA was added to a single-stranded DNA solution. Reaction mixtures (1 ml) contained 3 mg DNA, 2.94 µg ³H-labelled RNA (1,660 c.p.m.) and unlabelled competitor RNA. The reaction mixture was placed in a water bath at 70 °C and the salt concentration was adjusted to 0.4 M PBS. At C₀*t* 10,000, the incubation reaction was stopped by removing the glass tube and placing it into an ice bath. The hybridisation mixture was diluted with water to a concentration of 0 24 M PBS, and treated with RNase (50 µg ml⁻¹) at 37 °C for 30 min. After RNase treatment the reaction mixture was precipitated with cold 10% TCA. The precipitate was collected on Whatman GF/C glass filter, washed with adequate volumes of 5% TCA and with ethanol, dried and counted in a scintillation counter.

tion, similar results were obtained. As the hybridisation conditions used in these experiments are known to detect differences in the transcription of repeated DNA sequences, the above results may indicate negligible differences in the transcription of the repeated DNA sequences between the L and S fractions.

When the reaction mixture was incubated to C₀*t* 10,000 at 70 °C with a DNA excess, about 40–50% hybridisation was reached in the absence of an unlabelled competitor.

As shown in Fig. 1*b*, when the rapidly labelled RNA of the S fraction was competed with each unlabelled RNA of the L and S fractions, the unlabelled RNA of the S fraction was much more effective in competition than was the L fraction. These results are indicative of significant differences in the transcription of unique DNA sequences between the two cell types. These differences are statistically significant ($P < 0.05$). Therefore, it can be concluded that the neuronal and glial nuclei have the cell-specific RNA species. The proportion of RNA transcribed from repeated DNA sequences seems to be only a minor fraction of the rapidly labelled nuclear RNA and much of this nuclear RNA is transcribed from unique DNA sequences. As some parts of these latter RNA species pass to the cytoplasm as mRNA, cytoplasmic mRNA should be the product transcribed from unique DNA (refs 9 and 11–13). Further, these premessenger nuclear RNAs contain polyadenylate sequences[13,14]. Our present results may indicate the differences in such RNA species between two cell types. On the other hand, no differences are found in RNA transcripts from repeated DNA sequences which seem to be a minor fraction of the heterogeneous nuclear RNA with a small amount of premessenger RNA as described above. The function of such RNA transcribed from repeated DNA is not yet fully elucidated, although the hypothesis of Britten[15] is interesting. As the cytogenetical relationship between two cell types is close[16], it may be difficult to find the differences in such RNA using a membrane filter technique.

Recent reports on the saturation hybridisation experiment have shown that about 8% of mouse unique ³H-DNA is complementary to total brain RNA and that the complexity of the spectrum of RNA from other tissues is about 2%. Church and Brown[2] have suggested that these results reflect the diversity of cell types found in the brain. Our present results may be in agreement with their suggestion. On the basis of the experiment with the total RNA of malignant neural tissues, Grouse *et al.*[17] have reported that neuronal and glial cells exhibit roughly the same extent of transcriptional diversity. Their results may be related to the use of the saturation technique and the total quantities of respective tissues. In the context of our present results, it may be interesting that neurones contain the specific protein like 14, 3, 2 (ref 18) and glia also the specific protein like S100 (ref 18). It will be necessary to isolate and characterise these cell-specific RNAs.

We thank Mr K. Araki and Miss E. Kushiya for assistance.

Excision of thymine dimers from specifically incised DNA by extracts of xeroderma pigmentosum cells

SINCE the initial observations on defective DNA repair in fibroblasts cultured from patients with xeroderma pigmentosum (XP)[1,2], a large number of cases have been collected and studied in laboratories around the world The results of these studies indicate a surprising degree of complexity in the DNA repair defect(s) in this disease. At an early stage it became apparent that not all cell strains are totally defective in the excision repair of ultraviolet radiation damage in vivo, there being varying degrees of "leakiness"[3-5]. Cell fusion studies have since indicated that a number of distinct genetic complementation groups exist, suggesting a multigenic basis for the disease[6-9]. In addition, defects in photoreactivation[10] and in post-replication repair[11] of ultraviolet radiation damage in some XP strains have been reported.

If we confine our attention to those strains of XP cells that exhibit defects in excision-repair (ignoring for this study the variants which have normal excision repair[12,13] but defective post-replication repair[11]) then five distinct complementation groups, designated A,B,C,D,E, have been identified[6,7]. Only one patient in group B is currently known.

At present, little is known about the biochemical basis of the repair defectiveness of XP cells in culture, or of the various complementation groups. In all cases specifically examined, indirect studies suggest the presence of an endonuclease or endonuclease-related defect. The evidence on which this suggestion has been made includes the ability of XP cells to repair DNA strand breaks from ionising radiation[14,15] and alkylating agents[16,17], the failure of XP cells to repair damage to DNA bases that require endonucleolytic incision[17-19] and the failure of XP cells to excise dimers[2,20] or remove ultraviolet endonuclease-sensitive sites[21] from their DNA Direct demonstration of a defect in the incision step of repair by measurement of single strand breaks in DNA has not been achieved[22,23].

Since many of these studies were carried out in different laboratories, before complementation analysis began, it is not possible to state whether an apparent incision defect is characteristic of all complementation groups, but no exceptions have been reported except for the XP variant. Current understanding of the molecular mechanism of excision repair based on prokaryote models, calls for an endonucleolytic incision of DNA, excision of the damaged segment and repair synthesis. One might therefore expect that some cases of XP would show defects in the latter two steps. Nonetheless, the finding of a DNA incision defect in more than one complementation group is not inconsistent with the existence of multiple alleles, if the human cell ultraviolet endonuclease has multiple subunits and/or if other gene products are required for the endonuclease to function in human cells.

An alternative hypothesis first suggested by Haynes[24] is that the repair enzymes may function as a complex in a coordinated way, such that a defect in any one step would block the entire repair process. If this hypothesis were correct, then cases of XP defective in an excision nuclease or a DNA polymerase activity would still show a defect in the incision of ultraviolet-irradiated DNA and in vitro none of the enzymatic steps associated with excision repair should be demonstrable On the basis of this kind of model, it has been suggested that all the data currently available on XP cells is consistent with either a defective endonuclease or exonuclease[25].

To obtain direct evidence for the validity of the enzyme complex hypothesis and further information on the repair

Table 1 Characteristics of XP cell lines used for dimer excision ability

Cell line	Neurological symptoms	Level of unscheduled synthesis*	Complementation group
XP 12 (SV40)	yes	0	A†
XP 25 RO	yes	0	A†
XP1 PW	no	4-7%	C‡
XP2 NE	yes	33-51%	D‡
XP 21 SF	no	60-65%	E‡

*Measured by autoradiography of fibroblasts labelled for 3 h with ³H-thymidine (10 μCi ml⁻¹ 15.8 Ci mmol⁻¹) after irradiation with 50–100 erg mm⁻².

defects in XP cells, we have developed a cell-free system that excises pyrimidine dimers in vitro[26]. In our initial investigations[26,27] we reported the presence of an exonuclease activity in extracts of normal human cells in culture, which excises thymine dimers from ultraviolet-irradiated DNA previously incised with a dimer-specific endonuclease purified from bacteriophage T4-infected E. coli[28]. This activity excises thymine dimers in the 5'→3' direction, is stable to freezing, has a requirement for Mg^{2+} or Mn^{2+} and is sensitive to inhibition by SH-blocking agents. A similar activity has recently been purified from human placenta[29]. We have now examined extracts of XP cells for dimer excising activity on previously incised DNA from four of the complementation groups discussed above. Fig. 1 shows the results obtained with extracts of a human cell line (HeLa) and an XP cell line (XP 12 [SV40] RO). Table 2 shows the excision of thymine dimers by extracts of a normal and four XP fibroblast strains. The results of a number of such experiments indicate no significant differences in the specific activity of excision nuclease in any of the XP classes compared with normal cells.

These results lead us to conclude, first, that the hypothesis of a coordinated enzyme complex for performing excision repair is not applicable to excision of pyrimidine dimers in vitro: extracts of all XP classes can excise pyrimidine dimers from an exogenous DNA when the first step of repair is completed by the T4 phage coded endonuclease. Second, there seem to be no examples of XP cells defective in the excision step of excision repair in vitro. This lends further support to the observation that the biochemical defects in excision repair in this disease may be related to events pertaining to endonucleolytic incision of damaged DNA.

We offer these conclusions with the following reserva-

Fig. 1 Details of the experimental procedures are described in the legend to Table 2. Each incubation contained crude protein in the amount indicated. ○, ×P 12 (SV) RO; ●, HeLa.
Table 2 Thymine dimer excision activity in normal and XP cell extracts

Source extract	Complementa-tion group	Thymine dimers excised in 30 min (%)	Total acid-soluble nucleotides (%)
197 P (normal)	—	22	5.4
XP 25 RO	A	20	3.4
XP 1 PW	C	19	4.8
XP 2 NE	D	32	2.8
XP 21 SF	E	25	5.2

XP cells were obtained by skin punch biopsy and the normal fibroblast strain (197P) was obtained from foreskin. The cells were grown in minimal Eagles medium with 15% foetal calf serum (Gibco, Grand Island, NY) and 100 U ml^{-1} of penicillin and streptomycin at 37 °C in a 5% CO_2 atmosphere. Cells were collected with trypsin-EDTA and washed three times with buffered saline. Cell cultures were checked for mycoplasma by the method of Todaro *et al.*[30] and showed no contamination. Cell-free extracts (microscopic examination revealed complete disruption of cells and nuclei) were made in 0.15 M NaCl, 0 01 M Tris-HCl buffer *p*H 8.0 and 0.005 M β-mercaptoethanol with| 30 strokes of a Dounce homogeniser using a tight-fitting pestle. Incubation mixtures (0.1 ml) contained 22.5 nmol of ^3H-*E. coli* DNA previously ultraviolet-irradiated at a fluence of 334 J m^{-2} and incised with T4 ultraviolet endonuclease[28]. This DNA was shown to have endonucleolytic incisions on the 5' side of 80–95% of the thymine dimer sites. Also present in the mixture were $MgCl_2$, 0.1 M; Tris-HCl buffer, *p*H 8.0, 0.01 M and 140 μg ml^{-1} protein from the crude extract. Incubation was at 37 °C for 30 min. Reactions were terminated by the addition of 0.1 ml 10% cold trichloroacetic acid. The acid-insoluble fractions were hydrolysed and thymine dimer contents determined as described previously[31].

tions in mind. First, these studies have used cell-free preparations and we have no direct evidence that the enzyme activity or activities measured, function in dimer excision *in vivo*. Second, the substrate used consists of ultraviolet-irradiated *E. coli* DNA incised with an endonuclease purified from phage-infected cells. It is possible that the human UV endonuclease acts in a manner which precludes the action of the nuclease activity we have measured and creates substrate sites for a different enzyme. It is also possible that the excision step involves an additional factor(s) in order to accommodate the complexity of the chromatin substrate in living cells.

Regeneration of the photoprotein aequorin

THE photoprotein aequorin (molecular weight about 30,000) isolated from the bioluminescent jellyfish *Aequorea aequorea*[1-3] emits blue light (λ_{max} 470 nm)[4] by an intramolecular reaction in aqueous solution when Ca^{2+} is added, in the presence or absence of molecular oxygen[1]. This reaction has been postulated[5] to follow the scheme in (Fig. 1), in which an essential component H_2O_2 of aequorin is bound to the protein part in a form such as a peroxyacid or an α-hydroxyhydroperoxide which readily releases H_2O_2. Hypothesised roles for peroxide in aequorin (see recent review[6]) are consistent with this scheme. YC is a yellow chromophore of unknown structure, responsible for the colour of aequorin from which it has been isolated[5], and found to be different from other components in Fig. 1.

The luminescence reaction requires the binding of three Ca^{2+} to one molecule of aequorin[4]. The product is a blue fluorescent protein (BFP) that exhibits a fluorescence spectrum exactly corresponding to the blue luminescence of the Ca^{2+} triggered reaction[4]. In BFP, the light-emitting moiety (Fig. 1, compound I), which is not fluorescent itself in aqueous solution, binds to the protein part (dissociation constant 5×10^{-6} M)[7] yielding the fluorescent BFP (ref. 8). We have now found that the protein moiety of spent aequorin reacts with compound II in the presence of molecular oxygen, leading to regeneration of aequorin (Fig. 1). Compound II, initially found in aequorin in its enolised structure[5], is evidently the same as natural luciferin of *Renilla*[9]. We have named this compound coelenterazine[9] in view of its widespread occurrence in luminescence systems of coelenterates[6,9,10].

A sample of electrophoretically pure aequorin[3,4] was luminesced by addition of Ca^{2+}, and the resulting BFP was passed through a column of Sephadex G25 (Pharmacia) prepared with 0.01 M Tris-HCl buffer (*p*H 7.5) containing 0.01 M EDTA, to separate the protein moiety and compound I. The former eluted in the void volume, whereas the latter was adsorbed on the column. Treatment of this protein with a large excess of synthetic compound II (ref. 11), in the presence of molecular oxygen plus 2 mM 2-mercaptoethanol and 5 mM EDTA, at 5 °C, gave rise to Ca^{2+}-triggerable photoprotein. The yield of photoprotein was 50% after 25–30 min, and nearly 90% within 3 h, with reference to the amount of protein molecules. After 20 h the reaction mixture was passed through a column of Sephadex G25 (prepared as above) to separate photoprotein from reagents. The photoprotein thus obtained was identical to the original aequorin as evinced by absorption spectrum (λ_{max} 281 and 460 nm, $A_{460}/A_{281} = 0.030$), luminescence spectrum (λ_{max} 470 nm), luminescence activity (1.55×10^{15} photons ml^{-1} at 25 °C when A_{280} is 1.0 cm^{-1}), kinetics of luminescence in the presence and absence of air (Fig. 2), and chromatographic behaviour on DEAE-cellulose and Sephadex G100. Regeneration is thus confirmed; it was not influenced by various concentrations of EDTA or by the addition of H_2O_2, but it did not take place in an evacuated reaction vessel without oxygen.

When compound II was added to a solution of separated
Fig. 1 Postulated mechanism of luminescence[5] and regeneration of aequorin. Bound H_2O_2 in aequorin is tentatively shown as α-hydroxyhydroperoxide. After the luminescence reaction, YC in aequorin is reduced to a colourless form $YC \cdot H_2$, but the sulphydryl (SH) group(s) essential for light emission is ultimately unchanged. CO_2 in BFP may be bound to the protein.

protein moiety together with Ca^{2+}, or directly into spent aequorin, that is, into the solution of BFP containing Ca^{2+}, aequorin was regenerated and luminesced simultaneously as Ca^{2+} was already present. The result was thus a weak, continuous luminescence (Fig. 3). The rate of slow light emission in such circumstances obviously parallels the rate of regeneration of aequorin, in as much as the usual Ca^{2+}-triggered luminescence of aequorin is very fast (see Fig. 2). In the presence of 2-mercaptoethanol plus an excess of II, the weak luminescence continued for many hours, resulting in a total photon emission at least five times that of the fast luminescence of the aequorin originally used. In the absence of 2-mercaptoethanol, however, luminescence gradually died away, resulting in a total photon emission only 10-15% that which occurs in the presence of 2-mercaptoethanol. Thus, this reagent seems to protect the functional sulphydryl group(s) during regeneration.

According to the above, the protein moiety of spent aequorin

Fig. 2 Ca^{2+}-triggered luminescence of native aequorin (○) and regenerated aequorin (●). Curves for 10^{-2} (a), 10^{-4} (b) and 10^{-6} M Ca^{2+} (c) are offset at 1, 2, and 3 s, respectively, for 0 time. Luminescence was initiated by quick addition of 3 ml 10 mM Tris-HCl buffer (pH 7.2) containing calcium acetate to aequorin solutions consisting of 3 μl aequorin stock solution containing 0.2 mM EDTA (A_{280} 1.44 cm^{-1} for both native and regenerated aequorin) plus 0.3 ml water. To avoid contamination of the more dilute (10^{-4}, 10^{-6} M) Ca^{2+} solutions, plastic rather than glass containers and pipettes were used throughout, except for a Hamilton syringe to measure the aequorin stock solution. The absence of any effect due to the presence of oxygen is shown by data (▲) on luminescence of regenerated aequorin with 10^{-2} M Ca^{2+} in a vessel thoroughly evacuated by a vacuum pump. Temperature: 24 °C.
Fig. 3 Ca^{2+}-triggered luminescence of aequorin and regenerated aequorin: a, 4 ml 10 mM Ca acetate was added to 8.7 μg aequorin in 1 ml buffer at 5 min, followed by addition of 6 μg II in 20 μl methanol at 10 min; b, 8.7 μg protein moiety of BFP and 6 μg II were added to 1 ml buffer; the mixture was kept at 5° C for 3 h, then placed in the light-measuring apparatus at 0 min, and 4 ml 10 mM Ca acetate was added to this mixture at 15 min; c, 4 ml 10 mM Ca acetate containing 6 μg II was added to 1 ml buffer containing 8.7 μg protein moiety of BFP at 25 min; bubbling the mixture with Ar gas started at 45 min; Ar was switched to air at 50 min, then bubbling was stopped after 15 s. The buffer (pH 7.5) in all cases consisted of 10 mM Tris-HCl, 5 mM EDTA and 2 mM 2-mercaptoethanol. The amount of aequorin was estimated from A_{280} ($E1\%$-1cm = 27.0) (ref. 2). The amount of protein moiety of BFP was calculated assuming that aequorin yielded the same amount of the protein moiety. All luminescence measurements were carried out at 20 °C. The quick flash at 5 min is caused by native aequorin; all other light emissions are caused by regenerated aequorin.

can be regarded as an enzyme catalysing a luminescent oxidation of coelenterazine (II). In this view, aequorin itself must be considered to represent an intermediate, as hypothetically suggested by several investigators[6]. If so, by its known properties it is an indissociable intermediate[1,2] that is extraordinarily stable (in the absence of Ca^{2+}).

The extent to which regeneration takes place in the organism is uncertain, but the presence of coelenterazine enol-sulphate in the photogenic tissues of Aequorea in an amount equivalent to as much as 5% of the aequorin molecules[9] suggests that the photoprotein recycles in vivo as well as in vitro. Terminal steps in the generation of aequorin in vivo possibly follow the same pathway as regeneration.

The above results are interesting also in regard to the use of

aequorin luminescence as a fast, sensitive test for presence of Ca^{2+} in biological systems[12-19]. Inclusion of coelenterazine in the test system should prolong considerably the luminescence life of aequorin.

A recent paper[20] contains statements which amount to the suggestion that YC of the present paper is in effect *Renilla* luciferin. We have shown, however, that *Renilla* luciferin is actually identical to coelenterazine[9]. It should be emphasised that the absorption spectrum of YC (ref. 5) is significantly different from that of coelenterazine except for the one peak in the visible region. Moreover, recent mass spectrometric data (O.S. and F.H.J., unpublished) have demonstrated that YC and coelenterazine are in fact different compounds.

We thank Drs T. Goto and S. Inoue for a sample of synthetic coelenterazine, and the US National Science Foundation and Office of Naval Research for financial support.

Erratum

In the article "Computer simulation of protein folding" by M. Levitt and A. Warshel (*Nature*, **253**, 694; 1975) the wrong version of Fig. 4 was printed. The correct version is reprinted below.
Fig. 4 Simulation of PTI folding from an extended starting conformation with the terminal helix ($\alpha = 180°$ for all except 48 to 58 where $\alpha = 45°$). No knowledge whatsoever about native PTI is used during this simulation (apart from setting the terminal helix). The conformation was thermalised at the end of each minimisation except near cycles 490 and 730 when the energy rises slightly because the minimisation was restarted after rounding the torsion angles to one degree. In the first two thermalisations, each normal mode was perturbed in the plus direction to raise the associated energy to $R(n)kT/2$ with $T = 1,000$ K. In the other three thermalisations, the perturbations were randomly in the plus and minus directions but always such as to raise the energy by $kT/2$ with $T = 300$ K. (Because the random numbers are distributed uniformly rather than exponentially, these temperatures do not correspond to the macroscopic temperature.) The 8 ribbon diagrams, which show the C^α chain path, refer from left to right to the 8 conformations at the circled points on the r.m.s. deviation curve, respectively. The last five conformations have progressively lower energies and are each a little closer to the native structure ($E = -43.3$, -45.7, -46.0, -46.9 and -48.9 kcalorie mol^{-1}, respectively; r.m.s. deviation $= 6.08$, 5.7, 5.6, 5.4 and 5.3 Å, respectively). The solid dots at the end of a minimisation indicate that a perfect minimum was reached (r.m.s. gradient less than 10^{-6} kcalorie $mol^{-1} rad^{-1}$). One cycle takes about 0.6 s on an IBM 370/165 computer.

matters arising

PCB concentrations in North Atlantic surface water

CONCENTRATIONS of polychlorobiphenyls (PCBs) have supposedly[1] declined 40-fold over wide regions of the North Atlantic from levels of about 30 ng l⁻¹ in 1971–72, to 0.8 ng l⁻¹ in 1973–74. This decline has been attributed[1] to the restriction of sales of PCB for non-captive uses during the period 1970–73, both in Europe and in North America. Much as we would like to believe these conclusions, they seem unfounded to us, and they seem to ignore the dynamics of the PCB–seawater system.

From estimates of PCB concentrations in 0.3 µm filtered seawater from 41 North Atlantic stations, Harvey et al. estimated a standing stock of dissolved PCB in the upper 200 m of the North Atlantic of 2×10^4 tonnes (t) in 1972 (ref. 2) in addition to whatever quantity was bound up with <0.3 µm of particulate material; they suggested that the latter could increase the amount of PCB in the 1972 standing stock by 10%.

Using the reported 40-fold decline in the PCB concentration, and a model based on a simple exponential loss-rate we have derived a mean residence time, r, for PCB in seawater in the North Atlantic. Our model simulates the loss process on a daily basis by reducing the standing stock, S, by S/r. A range of values of r was tested to discover the value which reduced S ($= 2 \times 10^4$) by 97.5% ($= 40$-fold) at the end of 365 d. The model indicated a mean residence-time of just under 100 d. In order for such a system to sustain the reported standing stock of 2×10^4 t, this value of r requires an annual input of 7.3×10^4 t (representing the loss from the stock over 365 d).

That seems absurd in relation to what is known about the total production of PCB during the period 1960–71 (Table 1) because it suggests that a standing stock

results are not correct, so that the 1971–72 data (24–41 µg l⁻¹) are too high or the 1973–74 data (0.8–2.0 µg l⁻¹) are too low; or, second, that the extrapolation from individually correct data to a standing stock for the whole North Atlantic is at fault.

It seems relevant to note that three different analytical methods were used to obtain the two sets of data, that no evidence is presented on the repeatability of individual data and that, at least for the 1971–72 data, 36 of the 52 samples were collected with buckets at the water surface and so must have included an unknown and variable quantity of material from the surface microlayer which is known to be highly enriched with hydrocarbons even in the open ocean[3].

Further, if the results from the 1971–72 analyses proved to be too high to be representative of water between the surface and a depth of 200 m over the North Atlantic as a whole, it would also resolve the paradox that has been evident for some years between those data and the relatively low values (about 1.0 ng l⁻¹) reported from coastal waters of the generally rather contaminated California Current[4] and those (<10.0 ng l⁻¹) from the Irish Sea[5], a region likely to be relatively highly contaminated.

The extrapolation from the two sets of data to two levels of standing stock for the whole North Atlantic (which is based simply on an estimate of the volume of the 0–200 m layer of that ocean) also seems to be not very well founded. The data are log-normally distributed, and so extrapolation would have been more appropriate from the geometric rather than the arithmetic mean; such a statistical distribution is likely to be a result of the very high degree of variability within regions (Harvey[2] reports a range of 1–150 µg l⁻¹ over a distance of only 80 km in the open Atlantic) or to the fact that both the

Quinn et al.[3] are widely separated: in 1971 they came from a line between Newfoundland and Iceland, but in 1973 they came from the Sargasso Sea. We therefore suggest that the data and interpretations presented by Harvey et al.[1] are insufficient evidence on which to base the deduction that recent partial controls on uses of PCBs have already produced a dramatic decrease in the contamination of the upper layers of the open Atlantic Ocean.

HARVEY AND STEINHAUER REPLY—We disagree with Longhurst and Radford[1] that our analytical results are incorrect. After several comparisons of the different methods, analytical standards and reproducibility ($\pm$ 20%) we are quite certain that our data are correct as they stand. It is relevant that during 1971–72, when about 30 ng l⁻¹ PCB was being measured we were also measuring 1 ng l⁻¹ or less in tapwater and groundwater. Also, in 1973–74 we measured PCB concentrations of 30–300 ng l⁻¹ in polluted estuaries near Boston, USA, at a time when North Atlantic values had declined to 0.8–2.0 ng l⁻¹. Clearly, the methods were capable of determining PCB concentrations present in different water masses over a wide range of values during the period in question.

We now agree, however, that our previous extrapolation was not justified. In the light of some recent data it seems that each area of the North Atlantic (the central gyre, doldrums, trades, and so on) is characterised by clusters of similar PCB concentrations which roughly correlate with salinity, wind direction and latitude[2]. As we do not have data from north of 45° N since 1972, nor from south of 20° N before 1973, our extrapolation from an average concentration to the

Table 1 Global production (t × 10⁴) of PCB, assuming US production to be half of global production[6]

1960	1961	1962	1963	1964	1965	1966	1967	1968	1969	1970	1971
3.44	3.32	3.48	4.06	4.62	5.50	5.90	6.84	7.52	6.94	7.72	3.66

of the magnitude reported by Harvey et al. could only be achieved if the total world production of PCB were put continuously into the North Atlantic.

For a more reasonable explanation for this result, two possibilities should be considered: first, that the analytical

1971–72 and 1973–74 data comprise regional clusters of stations, each cluster being widely separated from others, so that there was little geographical correlation within or between the two sets of data. Even the two sets of data, one in each period, derived from the work of

entire North Atlantic was not warranted. In contrast, PCB concentrations have been measured regularly in the North American Basin during 1972–75. As this is the closest ocean basin downwind of the US industrial complex the large decrease observed there between 1972 and 1973 may only reflect changes in the North American PCB input and may have been the most rapid in the North Atlantic.

We intend to measure PCB concentrations north of 50°N during 1975 in waters more within the influence of European PCB losses.

Avian vision

IN an article[1] on the visual control of head movements by walking birds, Friedman quotes me as maintaining that a bird's head moves backwards as well as forwards during walking. This is not so. In 1931 observation of hens had shown me that, as Friedman has proved for pigeons, the head of a walking hen is thrust forwards as rapidly as possible and then remains stationary while the body of the bird catches up. It seemed to me quite clear that this enables the hen to have a succession of sharply defined pictures of its environment rather than the continuously slightly fuzzy picture which would be obtained from steadily moving eyes.

Humans circumvent this problem differently. They fix visually upon a succession of points for varying times according to their momentary interest, and use a reflex capacity to control eye positions to compensate for bodily movement.

Most birds have a much larger area of high definition than humans, backed by a much less versatile data processor, and may find it advantageous to attend only to those objects in their environment that are moving independently. These can be distinguished from a complex background only when the eyes are stationary with respect to that background and are not confused by the apparent backward displacement of the nearer objects which will occur as a result of parallax while the eyes are moving.

In my article[2] I was not concerned at all with the head movements of walking birds but with the frequent up and down movements of the heads of stationary birds. This, I suggested would not only give feeding birds

longer ranges of vision—which it by no means always does—but would enable birds to use parallax to obtain a three-dimensional picture of their surroundings.

Binocular stereopsis is available to most birds, with their sideways-looking eyes, only over a very narrow field of forward vision, and with an extremely short 'baseline' between the eyes. Observation of the changes of the retinal image as a bird raises and lowers its head, however, provides the bird with a much longer baseline and gives the possibility of three-dimensional vision over the whole field of view of both eyes—often nearly 360°.

Plume spacing and source

SINCE the average distance between island-arc volcanic centres (~70 km) is approximately equal to the depth to the magma source (~100 km), Lingenfelter and Schubert[1,2] have suggested that the typical distance between hot spots (~3,000 km) is approximately equal to the depth to their source. Thus, they infer that the region of instability giving rise to the initially solid plumes of mantle material is near the core–mantle boundary. Certain fluid dynamic results may show this inference to be untenable.

In the case of island-arc volcanism[3], andesitic magma is generated along the Benioff Zone at a depth of about 100 km. The magma is much less dense than the overlying peridotitic mantle material and this two layer system, andesitic magma beneath peridotitic mantle, is gravitationally unstable. This situation is analogous to that of a layer of oil underlying a layer of water, and represents a type of fluid instability commonly known as Rayleigh–Taylor instability[4–6].

When perturbed from equilibrium, the less dense, lower fluid penetrates the overlying fluid at discrete and, ideally, evenly spaced points. This is the case in both two and three dimensions[4,5]. The characteristic wavelength of instability is dependent on the depth to the source layer (or thickness of the upper layer) only if the thickness of the source layer is greater than one tenth of the depth to the source[7]. That is, once the upper layer is 10 times thicker than the lower buoyant layer the dominant wavelength of instability is independent of the depth to the buoyant layer. In island arcs, judging from the

exceedingly small quantity of lava observed at the surface, the thickness of the magmatic layer is, surely, much less than 10 km. For those cases, the spacing of the volcanic centres is given by[4]

$$\lambda = (2\pi h_2/2.15)(\eta_1/\eta_2)^{1/3}, \text{ for } h_1 > 10h_2$$

where: λ = the dominant wavelength or spacing of volcanic centres; h_1 = the thickness of higher density layer; h_2 = the thickness of lower density layer; η_1 = the viscosity of denser layer (mantle); η_2 = the viscosity of lighter layer (andesitic magma).

By estimating roughly the contrast in viscosities ($\eta_1/\eta_2 = 10^9$), and from the observed spacing of the volcanic centres (~70 km), the magma layer in the case shown was probably a few tens of metres thick at the time of instability.

In the case of plumes, assuming, as did Lingenfelter and Schubert[1], that the process of instability is similar to that operative in island arcs, if the source layer is near the core–mantle boundary it must be greater than about 300 km thick for the plume spacing to reflect the depth to the source (that is, 3,000 km). Seismic evidence seems to indicate that a low density layer of this thickness cannot be present in the lowermost mantle. On the other hand, if it is assumed that the depth to the buoyant layer, wherever it is, is greater than 10 times the thickness of the buoyant layer itself, the thickness of that layer can be calculated from the relationship given already. For $\lambda = 3,000$ km and $\eta_1/\eta_2 = 10^3$, the buoyant layer thickness is about 100 km, whereas for $\eta_1/\eta_2 = 10^6$ it is about 10 km. A layer 10–100 km thick could be located seismically. Since the existence of a low density layer is a necessary condition for this type of fluid instability, which seems inherent in the plume theory as envisaged by Morgan, it is of paramount importance to ascertain its presence.

In conclusion, the distance between island-arc volcanic centres tells us little about the depth to the magma source and this is also probably true for the spacing between plumes if they arise from a Rayleigh–Taylor type fluid instability.

reviews

LIND'S *Studies in Pre-Vesalian Anatomy** is a massive work; a stout quarto of more than 300 double-columned pages, which has been meticulously researched in libraries and archives in Europe and America. The fruits of Professor Lind's labours of the past 12 years are abundant. We are given 16th century documents—wills, letters, university and municipal records —which previously have never been published. We are given biobibliographies of eight pre-Vesalian anatomists. Finally, Lind provides elaborately annotated translations of six anatomical treatises originally published between 1497 and 1559. The result is a wonderfully full picture of the state of anatomy in the half century before Andreas Vesalius' *De humani corporis fabrica* (1543) transformed the subject. While Vesalius' genius is actually thrown into relief by comparison with his contemporaries, Lind's study documents the rich and vibrant anatomical tradition which preceded the *Fabrica*. Vesalius did not emerge from a vacuum.

With two exceptions, all of these pre-Vesalian anatomists were Italian, a fact which underscores the importance of the Italian universities in 16th century medicine. One of the exceptions was Andrés de Laguna (1499–1560), a peripatetic Spaniard who spent nine years in Italy. De Laguna wrote more than 30 books, including the *Anatomica methodus* (1535) which Lind has translated, though this is perhaps the least original of the texts which he has chosen. Though de Laguna himself was a figure of considerable fame, his *Anatomica methodus* was inferior to various similar works which also preceded Vesalius. One of these was Niccolò Massa's *Liber introductorius anatomiae* (written by 1536 though dated 1559 on the title page), also translated in the present volume. Educated at Padua, Massa (1499–1569) was an active physician who practised in his native city of Venice and who wrote widely on plague and syphilis. Whereas de Laguna returned solely to the ancients for authority, Massa was aware of the tradition of anatomical study in the west,

Groundwork for a transformation

that had begun with Mundinus (1275?–1326). Mundinus was also revered by Berengario da Carpi (1460–1530), whose *Commentary on Mundinus* (1521) is summarised in this volume. Lind published an annotated translation of Berengario's more famous *Short Introduction to Anatomy* (the *Isagogae breves* of 1522) in 1959.

Berengario was one of a group of several outstanding anatomists who were prominent between the time of Mundinus and Vesalius : a group which included Gabriele Zerbi (1485–1569), Alessandro Achillini (1463–1512) and Alessandro Benedetti (1450?–1512). Lind has translated Achillini's *Annotationes anatomicae* (1520) and Benedetti's *Anatomice* (1502). Lind's work is rounded off with translations of Johannes Dryander's famous, short *Anatomia capitis humani* (1536) and Giovanni Battista Canano's equally familiar *Musculorum humani corporis picturata dissectio* (1541?). The well known illustrations of these latter two works are also reproduced.

From this summary the richness of Lind's work should be apparent. Lind provides the material necessary to any consideration of the development of anatomy between about 1500 and 1540. His annotations point back to the sources—classical, Arabic, and contemporary—of these pre-Vesalian anatomists He notes the philosophical preoccupation of most of these figures, several of whom were equally at home in the world of 16th century Aristotelianism In fact, part of Vesalius' suc-

cess resulted from the single mindedness with which he pursued anatomy; many of his talented contemporaries lost depth because of their eclectic and catholic enthusiasms; the anatomical treatises which Lind has translated generally present only a fraction of those anatomists' total outputs. His translations are lucid without being anachronistic. Where appropriate, he gives modern anatomical equivalents in parentheses, but he never tries to make these texts appear more modern than they really are. The short, introductory biographical studies of his subjects generally contain new material and full assessments of modern secondary literature.

In sum, this fine work tells us a great deal about the anatomical milieu in which Vesalius worked. It helps us see Vesalius' undoubted genius in clearer perspective. Though Professor Lind's bibliographic enthusiasm will appeal only to a handful of specialists, the work as a whole deserves a wide audience. Together with his earlier translations of Berengario and of Vesalius' *Epitome,* it permits the Latinless reader to appreciate for himself the development of anatomy in the first half of the 16th century. Translation and annotation may not be the most exciting part of scholarship, but they can be most exacting, and Professor Lind possesses the tenacity and erudition of the ideal translator. At $18.00 his latest book is an unusual bargain at a time when book bargains are few and far between. **W. F. Bynum**

Drug effects

Handbook of Drug and Chemical Stimulation of the Brain: Behavioural, Pharmacological and Physiological Aspects. By R. D. Myers. Pp. xvi+759. (Van Nostrand Reinhold: New York and London; Medical Economics: Oradell, New Jersey; February 1975.) £19.90.

TECHNIQUES for the direct administration of drugs into the cerebrospinal fluid, or into discrete areas of the central nervous system (CNS) have been in use for some time and have proved increasingly popular. The apparent directness and disarming simplicity of this approach to the examination of the CNS pharmacology of various bodily functions or behavioural processes has been particularly attractive to many research workers in the fields of physiological psychology and neuroendocrinology. This volume describes the many practical difficulties and pitfalls associated with this approach.

The main advantages of the direct administration of substances into the CNS are, first, that one may examine the effects of compounds that do not readily penetrate the blood–brain barrier after systemic administration and, second, that by localised applications one may hope to localise a particular drug action to some particular neuronal system in the CNS. The approach suffers, however,

from severe practical limitations. Unless very small volumes of fluid are injected, the spread of substances may be far too great to allow localisation. It is also difficult to judge what an appropriate dose of injected material should be. If compounds that have highly selective pharmacological actions on peripheral organs are injected in high local concentrations into the CNS, the observed effects may result from the non-specific toxic or membrane stabilising effects commonly found in many drugs. The absolute specificity of action of any drug is a myth that many of those engaged in research in this area have found beguiling.

In spite of the practical and theoretical difficulties, there is little doubt that research of this type has many useful applications. Although sophisticated methods exist for the micro-application of drugs and other substances onto single neurones in the CNS by micro-iontophoresis, one could only expect to elicit observable changes in behaviour or physiological functions after the exposure of much wider populations of neurones to drug stimulation or inhibition. Dr Myers is an acknowledged authority in this area and he has prepared a useful and scholarly compendium of the literature. He discusses in detail the principles and experimental methods in current use, and reviews the results obtained in attempts to manipulate a wide variety of bodily functions or behavioural states, including the control by the CNS of cardiovascular and respiratory functions, neuroendocrine relationships, sexual behaviour, body temperature, hunger, thirst, sleep, arousal, pain and cognitive functions. Each topic is dealt with in sufficient detail to justify the use of the term 'Handbook' in the title of the volume.

The book is amply illustrated, and each section has a "Master Table" summarising the available results. It is also liberally documented, with more than 1,400 references. Unfortunately, its value is diminished greatly by the fact that references cover the literature in detail only up to early 1972; this results in what seems to be a curiously dated view on some issues. For example, the evidence that cholinergic mechanisms play a rôle in learning and memory is reviewed in some detail, whereas the rôle of monoamines is dealt with in half a page. The latter is one area in which much has happened since 1972.

Dr Myers has presented facts and has not, to any extent, aimed to integrate psychological, pharmacological and physiological findings.

The author has produced the first detailed survey of an active and often poorly understood area. The volume will certainly be a useful reference work for those interested in this field.

S. D. Iversen

Drugs and Behaviour: A Primer in Neuropsychopharmacology. By Ernest L. Abel. Pp. ix+229. (Wiley-Interscience: New York and London, October 1974.) £7.55.

THE word 'primer' was originally used at the time of the Reformation to describe a prayer book or devotional manual for the use of the laity. Only later did the term acquire its common connotations of inky schoolroom, and the plain child's introduction to simplified truths.

A primer in neuropsychopharmacology might be expected to fulfil something of both these useful functions. The members of the laity who are not specialists in this particular science will be grateful for a reliable and intelligible guide to esoteric mysteries; and those who are in the graduate schoolroom, beginning the specialist study of this subject will be grateful for an accurate professional introduction.

At first glance this book has much to recommend it under both headings. It is eminently readable, and its author has natural gifts as a master of exposition. Illustrative examples are well chosen to exemplify general scientific principles—hunger as an adrenergic mechanism, the cholinergic mediation of water intake, serotenergic mechanisms and sexual behaviour. Headings and sub-headings order the matter well. Graphs are introduced at the apt moment, and are clear in the messages they carry. All in all, the immediate impression is of a simple textbook of considerable substance and expert presentation.

Closer reading brings some disappointments. The 'psycho' element in the neuropsychopharmacology (a truly Germanic word), receives scant treatment. The word 'placebo' is not to be found in the index, and nowhere does the influence of set and expectation receive adequate attention.

And as one gets deeper into the text so many errors and ommissions come to light that one begins to feel that the book has been contrived as basis for a game of 'spot the deliberate mistake'. THC is described as "the" active material in cannabis. The picture of amphetamine psychosis remains undescribed and classical work on the matter is ignored and unreferenced. The description given of schizophrenia would make Bleuter turn in his grave, and is not only misleading but damagingly misleading. The sharp differentiation drawn between psychological and physical dependence must be described as nonsense.

In short, the author should be encouraged to produce as a second edition of this readable and essentially worthwhile book (which ought to reach many editions) a text which will neither mislead the laity nor misinform the schoolroom. Otherwise anathema, and a black mark.

Griffith Edwards

Generally animals . . .

Animal Physiology: Adaptation and Environment. By Knut Schmidt-Nielsen. Pp. xvi+699. (Cambridge University Press: London, March 1975.) £7.25.

No animal exists, or can exist, independently of an environment. It may logically be argued, therefore, that all physiology is environmental physiology, for physiology is concerned with the functions of living organisms. The book under review deals at an elementary level with the familiar subjects of physiology, such as respiration, circulation, digestion and so on. Its 13 chapters are grouped according to major environmental factors: oxygen; food and energy; temperature; and water. Finally, movement, information, and integration are discussed, and it is shown how these functions are correlated and controlled in the living organism. There are six appendices and a comprehensive index. Although published by the syndics of the Cambridge University Press, the book has been printed in the United States of America and uses trans-Atlantic conventions and spelling.

As in his earlier books, the Professor of Physiology at Duke University writes with a clarity that imparts beguiling simplicity to quite complex concepts. He states in the preface that his latest effort was written in "anger and frustration" because he was unable to give his students a book which, in simple words, says what he finds "exciting and important in animal physiology, that deals with problems and their solutions, that tells how things work". He has succeeded in producing just such a book, and it will doubtless satisfy quite precisely the requirements of American undergraduate syllabuses. As far as the British market is concerned, however, I fear that the level may be a trifle too elementary.

The field of environmental physiology is now so vast that not even this large text-book can avoid being somewhat superficial. There are plenty of exciting ideas, but they are discussed too simply, and their documentation is rather inadequate. The selection of references, which "vary from brief and simple essays to large, comprehensive treatises", seems arbitrary and erratic. In places, too, there are signs of untoward haste in the writing; for example: "The degree of heating that a lizard can attain by heating up in the sun can be spectacular" (p. 358); and: "For aquatic insects the problem is to eliminate excess water and, as was mentioned above, this problem is usually handled by the kidney or equivalent excretory organ" (p. 418–9).

It is easy to cavil at the efforts of others: and the wider an author's vision, the easier it becomes to criticise his work on points of detail. There are, naturally, many aspects both of fact and of emphasis, with which other physiologists and zoologists may disagree—but this should not blind them either to the magnitude of Schmidt-Nielsen's conception or to the skill with which he has realised it. **J. L. Cloudsley-Thompson**

Zebrasoma, the sail-finned surgeon fish. From *The Guinness Guide to Underwater Life.* By Christian Petron and Jean-Bernard Lozet. 224 pages including over 100 colour illustrations and 280 in black and white. (Guinness Superlatives: Enfield, April 1975.) £6.95.

. . . particularly men

Physiology of the Human Body. By J. Robert McClintic. Pp. xxvii+588. (Wiley: New York and London, January 1975.) £6.80.

A MAJOR difficulty confronting any reviewer of this book is that of indicating clearly the type of reader to whom it should appeal, especially as the author states that it is directed at "all levels of reader" including those "planning to enter a health-orientated profession".

Among those professions, however, medicine is not specifically mentioned, and, in fact, the book is not one which could be recommended to a medical student as his working text since too many topics are treated superficially without sufficient attention to experimental evidence. The author has, however, produced a masterpiece of didactic compression which is commendably free from serious inaccuracies.

The text is liberally embellished with exceptionally clear tables and figures, often in the multicolour format familiar to readers of *Scientific American,* to which frequent reference is made in the bibliography. A most valuable feature of the book is a series of foldover plates depicting the structure of the human body layer by layer, and some might think that a study of these could save a great deal of time commonly spent in the dissecting room.

So much information is crammed into some 550 pages that redundancy is minimal and, therefore, great concentration is demanded of the reader. To aid him in monitoring his progress, however, each chapter concludes with a summary and a set of questions. Much attention is given to diseased states (presumably in the interest of "relevance") but the wisdom of including a thumb-nail sketch of the symptomatology of acute appendicitis is debatable. Likewise, an attempt to summarise biochemistry in a 12 page appendix, composed almost entirely of structural formulae, seems ill-judged, as does the inclusion of an elaborate table listing the symptoms of drug abuse and providing a key to junky slang; and the glossary at the end of the book usurps the function of the lexicographer by including such definitions as "quality—the nature and characteristic(s) of something". Misprints are rare but an eye-catching example amongst the questions on the digestive tract reads as "Discuss the importance of the lover in body function".

The growth in popularity of courses in human biology in both schools and universities may well ensure for this book a large market. **R. V. Coxon**
Mathematical tools

The Mathematics of Diffusion. Second edition. By J. Crank. Pp. viii+414. (Clarendon: Oxford; Oxford University Press: London, March 1975.) £12.50.

THIS volume could be regarded more as a tool kit than a book. Most of the content comprises a collection of mathematical methods for the analysis of diffusion problems, together with the solutions of the appropriate equations for many common situations. As mathematical results tend to be less transient than those of most other sciences, the bulk of the book is unchanged from the first (1955) edition, save for the addition of new references. In this new edition there are many cross-references to its alter-ego *The Conduction of Heat in Solids* by Carslaw and Jaeger; the latter volume presents a wider range of solutions to the diffusion equations and Crank has chosen those which are most appropriate to diffusion problems.

New material in this edition includes a chapter on non-Fickian diffusion, which provides an interesting review of solvent diffusion in glassy polymers, but it is somewhat out of place in this book in that it is inconclusive. A new chapter on diffusion in heterogeneous media is particularly timely as composite materials have become so widely used. The chapter

on numerical methods has been extensively revised to allow for the dramatic effects of developments in digital computers. Sadly, however, several diagrams of quaint analogue calculating machines have been lost in the process. This chapter is too brief, given that it is now often easier to compute a numerical solution than to derive the analytical solution, if one is not too proud. The challenge to a book of this kind is to provide enough detail to allow the average user to write the programme without consulting other sources. Crank dodges this challenge and simply gives a well referenced outline of the available methods.

This volume is a worthy successor to the first edition and will undoubtedly become an indispensable reference source for all who are concerned with diffusion problems.

P. D. Calvert and N. C. Billingham

Dynamic patterns

Dynamic Patterns of Brain Cell Assemblies. By A. K. Katchalsky, V. Rowland and R. Blumenthal. Pp. 187+viii. (MIT Press: Cambridge, Massachusetts, and London, 1974.) $15.00; £7.50.

WHAT is meant by "dynamic patterns"? In the present context the expression implies the idea that systems are made up of a complex hierarchy of smaller and larger "flow patterns" in which "things" are self-maintaining features of the flows. The concept also implies that the flow patterns can undergo sudden flip-over alterations, or translations, to new stable self-maintaining arrangements. Thus, one could say that the world is made up of complexes of movements, or dynamic patterns.

How important are these dynamic patterns? Are they merely biomathematicians' fantasies—intellectual toys—or are they of fundamental significance in biology? This book reports on a Neurosciences Research Programme Work Session, held in 1972, when various neuroscientists came together to consider the phenomenology of dynamic patterns and their relevance to neurobiology. Examples of dynamic patterns are presented from many fields including biology—the cellular structure that develops in a heated dish of spermaceti oil, self-maintaining cloud patterns, the well known Beloussov-Zhabotinsky reaction, and so on. Indeed, the invocation of dynamic patterns, or "cooperative non-equilibrium phenomena" is fashionable in fields as diverse as molecular interactions, developmental biology and sociology. My feeling is that these phenomena are likely to be of great significance, particularly for developmental biology and neurophysiology, and this book provides a useful introduction for non-specialists.

R. M. Gaze

Global tectonics and fossil fuel

Petroleum and Global Tectonics. Edited by Alfred G. Fischer and Sheldon Judson. Pp. xii+322. (Princeton University Press: Princeton and London, May 1975.) Cloth, £8.70; paper, £4.45.

AT the present time the surest way to get any geological manuscript into print is to postscript the title ' . . . and Global Tectonics'.

This volume, *Petroleum and Global Tectonics,* contains nine papers presented at a conference held in 1972 to honour Hollis D. Hedberg of Princeton University. The papers cover plate tectonics (Bullard), heat flow and vertical movements of the crust (Morgan), the origin and growth of basins (Fischer), rift valley basins and the sedimentary history of trailing continental margins (Kinsman), the petroleum and plate tectonics of the southern Red Sea (EXXON), marine sediments, geosynclines and orogeny (Curray), geochemical formation of oil (Erdman), geothermal gradients, heat flow, and hydrocarbon recovery (Klemme), and the distribution and geological characteristics of giant oil fields (Moody).

The idea of choosing a conference theme of interest to both academic and industrial geologists is highly commendable. But the academic and industrial authors seem to have been mutually embarrassed and to have been uneasy about the theme. Sir Edward Bullard thought the impact of plate tectonics on petroleum exploration was "rather weak" (p. 17), and Moody was similarly perplexed: 'I have some difficulty in trying to relate giant oil fields to the "New Global Tectonics" *per se'* (p. 314).

The net result is that most authors have gone off and 'done their own thing', either writing about global tectonics or about petroleum, but seldom about both.

It is only in the papers by the Exxon group, Klemme and Moody, that the two topics of petroleum and global tectonics are actually integrated, and very successfully so. The material for these three contributions is largely taken from back numbers of the *Oil and Gas Journal* and from the *Bulletins* and *Memoirs* of the *American Association of Petroleum Geologists.*

The volume does include, however, several excellent papers on sedimentary basins, geothermal gradients, modern marine sedimentary environments, rift valleys and the origin of oil.

The book is attractively produced and the illustrations are ample and clear.

R. C. Selley

obituary

Constantinos Doxiadis, known for his planning projects in a number of developing countries, has died in Athens at the age of 62.

Born in Bulgaria, he studied architecture at Athens Polytechnic and obtained a doctorate in engineering at Charlottenburg Technical University, Beira. He was director of the Athens Technological Institute and founder of the World Society of Ekistics, a term, coined by him to describe the interdisciplinary science of human settlements. He promoted a unique and valuable series of conferences on town planning studies, held annually in Athens and the Greek islands during the past dozen or so summers. To these Delos symposia—probably Doxiadis' primary contribution to his field—he attracted many leading exponents of different disciplines, who would not otherwise have had the opportunity to exchange ideas. Doxiadis was, at the time of his death, preparing a number of documents for the United Nations conference on human settlement, to be held at Vancouver in 1976.

Elizabeth L. Hazen, the coinventor of Nystatin, the first antibiotic successful in combating human fungal diseases, died in Seattle at the age of 89.

The greater part of Dr Hazen's career was spent with the state Health Department's division of laboratories and research. She and her coworker there, Dr Rachel F. Brown, screened hundreds of soil samples in the search for new antibiotics, finally tracing a microorganism that produced the antibiotic which became known as Nystatin. She received her doctorate in bacteriology from Columbia University, after graduating from the State College for Women in Columbia, Mississippi, and also served as an investigator in the department of dermatology at Columbia University College of Physicians and Surgeons.

Sir Geoffrey Ingram Taylor, a mathematician who made valuable contributions to engineering and geophysics, has died at the age of 89.

Sir Geoffrey had mainly been concerned with abstract hydrodynamical themes and later progressed to research in the practical problems of geophysics and meteorology. He was formerly Yarrow Research Professor of the Royal Society, of which he became a fellow in 1919. In 1913, he was meteorologist to the Scotia Expedition to the North Atlantic, and in France during World War I, he served as meteorologist to the RFC. He resumed this appointment during World War II and studied the motions of the air, and the cause and effect of eddies —many of these problems were applicable to aircraft. He was also involved in the design of better parachutes. He worked with the group which caused the first nuclear explosion at Los Alamos, New Mexico in 1944 and in that year he was knighted. Later in 1944, he won the Copley Medal, the senior award of the Royal Society, for contributions to aerodynamics and the structure of metals.

Joseph Proudman, CBE, FRS, the distinguished mathematician and oceanographer, has died at the age of 86.

Professor Proudman first studied the dynamics of tides at Trinity, Cambridge, and this was to become his main scientific interest. He returned to Liverpool, where he had taken his first degree, as a lecturer in 1913, and was appointed the first professor of applied mathematics in 1919. In 1933 he transferred to the chair of oceanography, which he held until his retirement in 1954. In 1916 Horace Lamb asked Proudman to assist him in preparing a report for the British Association on the state of research on ocean tides. This led him to found the Tidal Institute (now Bidston Laboratory of the Institute of Oceanographic Studies), concerned with all aspects of tides. The Institute acquired an international reputation for its tidal prediction services as well as for fundamental research. He was pro-vice-chancellor of Liverpool from 1940–46. He was a fellow of the Royal Society, which awarded him the Hughes Medal in 1957. He acted as secretary of the International Association of Physical Oceanography and as president from 1951–54.

announcements

Award

The Canadian Public Health Association has awarded the 1975 **ORTHO Award** to **J. E. F. Hastings** for his research in health services, planning and education.

Appointments

The National Environmental Research Council has appointed **A. W. Woodland** as director of the Institute of Geological Sciences.

Michael Sela has been elected president of the Weizmann Institute of Science in Rehovet, Israel.

International meetings

September 1–2, **Molecular beam kinetics,** Heriot-Watt University, Edinburgh (Dr A. R. Burgess, Department of Chemical Enginering, University College London, Torrington Place, London WC1E 7JE, UK).

September 1–3, **Thermodynamical properties of gravitational fields,** Newtown, mid-Wales (B. F. Schultz, Department of Applied Mathematics and Astronomy, University College, PO Box 78, Cardiff CF1 1XL, UK).

September 1–3, **Industrial crystallisation,** Usti Nad Labem, Czechoslovakia (Dr Sci Ing Nyvlt, Research Institute of Inorganic Chemistry, Revoluni 86, CS400, 60 Usti Nad Labem, Czechoslovakia).

September 1–4, **Electronic properties of solids under high pressure,** Louvain, Belgium (Luan Gervan, Laboratories of Solid State Physics, Department of Physics, Celestunenlaan 200D, B30/0, Leuven, Belgium).

September 1–5, **Charles Lyell centenary symposium,** London (J. C. Thackeray, Institute of Geological Sciences, Exhibition Road, London SW7 2DE, UK).

September 1–5, **Low energy electron diffraction and electron spectroscopy of solids,** Budapest, Hungary (Secretariat, LEED and Electron Spectroscopy of Solids Conference, Research Institute for Technical Physics, 1325 Budapest, PO Box 76, Hungary).

September 1–5, **Luminescence,** Tokyo, Japan (S. Shionoya, Institute of Solid State Physics, Tokyo University, 7221 Roppongi, Minato-ku, Tokyo 106, Japan).

September 1–5, **Combustion,** Orleans, France (Secretariat of the second European Symposium on Combustion, CRCCCHT–CNRS, Avenue de la Recherches Scientifique, CEDEX F45045, Orleans la Source, France).

September 1–5, **Computer education,** Marseille, France (AFCET, Immeuble Centre Dauphine, Place du Marechal de Lattre de Tassiguy, Paris 16e, France).

September 1–5, **Controlled fusion and plasma physics,** Lausanne, Switzerland (F. Hofmann, Centre de Recherches en Physique des Plasma, Ecole Polytechnique Federale de Lausanne, Avenue des Bains 21, CH1007 Lausanne, Switzerland).

September 1–5, **Drug abuse,** London (International Council on Alcohol and Addictions, Box 140, 1001 Lausanne, Switzerland).

September 1–5, **Mechanics in reactor technology,** London (Mr H. M. Carruthers, Associated Nuclear Services, 14–16 Regent Street, London SW1Y 4PH *or* British Nuclear Energy Society, 1–7 Great George Street, London SW1P 3AA, UK).

September 2–4, **Quantum electronics,** Oxford (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

September 2–4, **Energy utilisation and conservation,** East Kilbride (Conference Organiser, Birniehill Institute, National Engineering Laboratory, East Kilbride, Glasgow G75 0QU, UK).

September 2–5, **Electronic circuit techniques,** Canterbury, UK (Conference Department, Institution of Electrical Engineers, Savoy Place, London WC2R 0BL, UK).

September 2–6, **Cell differentiation,** Copenhagen, Denmark (DIS Congress Services, 3 Knabrostraede, DK 1210 Copenhagen, Denmark).

September 2–6, **Neurochemistry,** Barcelona, Spain (Dr J. Sabater, Instituto de Bioquimica, Calle Roberto Bassas 1, Barcelona 14, Spain).

Person to Person

'Yeti' discovered in Bhutan

A mummy-like object found in the state of Bhutan in the Himalayas and photographed by Pushkar Singh, who believes that it is the remains of a 'yeti' or abominable snowman. He would be grateful for any comments from readers who may have come across such an object on their travels (82 Mehdipatnam Colony, Hyderabad 500028, Andhra Pradesh, India).

Disaster message. Research group invites voluntary involvement of people from all disciplines interested in improving disaster assessment and relief including possible short term overseas surveys of up to 3 months (London Technical Group, 41 Queen's Gate, London SW7, UK, tel. no. 01–589 9076 ext. 14).

Immunodeficiency – cancer. Any physicians who have treated persons with primary immunodeficiency diseases who have subsequently developed cancer or who know of such cancer cases, are encouraged to register them in an international immunodeficiency–cancer registry. Information on patients confidential, data from the registry available to all participants (B. D. Spector *or* J. H. Kersey, Immunodeficiency–Cancer Registry, Box 609 Mayo, University of Minnesota, Minneapolis, Minnesota 55455).

September 3–5, **Microtubules and microtubular inhibitors,** Beerse, Belgium (M. Borgers *or* M. de Brabander, Janssen Pharmaceuticals, Research Laboratories, 2340–Beerse, Belgium).

September 3–6, **Lipoproteins and hyperlipidemies,** Lisbon (Professor M. J. Halpern, Department of Biochemistry, Faculty of Medicine of Campo Santana, Lisbon, Portugal).

September 3–8, **Artificial intelligence,** Tbilisi, USSR (Professor E. Sandewall, General Chairman IJCAI–75, Artificial Intelligence Laboratory, 545 Technology Square, Cambridge, Massachusetts 02139).

September 4–9, **Stereology,** Gaithersburg, USA (Fourth International Congress for Stereology, Organising Committee, Dr G. A. Moore, National Bureau of Standards, 31203, Washington DC 20234).

September 7–9, **Conservation for decision makers,** Kinshasa, Zaire (International Union for the Conservation of Nature, 1110 Morges, Switzerland).

September 8–10, **Engineering and food quality,** Cambridge, UK (Dr R. Jowitt, National College of Food Technology, St George's Avenue, Weybridge, Surrey, UK *or* Gesselschaft Deutscher Chemiker — Geschaftsstelle D6000, Frankfurt, M90 Postfach 900440, German Federal Republic).

September 8–11, **Gas dynamics of explosions and reactive systems,** Orleans, France (Centre National de Recherche, Scientifique 45045, Orleans-Cedex, France).

September 8–11, **Electron microscopy and analysis,** Bristol, UK (Dr J. E. Steeds, H. H. Wills Physics Laboratory, University of Bristol, Bristol BS8 1TL, UK).

September 8–11, **Marine natural products,** Aberdeen, UK (Dr J. F. Gibson, The Chemical Society, Burlington House, London NW1V 0BN, UK).

Miscellaneous

Vision research. In celebrating their 350th anniversary, the Worshipful Company of Spectacle Makers proposes to award a limited number of research fellowships (up to £3,000 per annum for up to 3 years). Intended as personal support only—the recipient's university or place of research will be expected to provide working accommodation, apparatus and facilities.

July 24, 1975

Let's hear it for the PhD

EIGHTEEN months ago the House of Commons Expenditure Committee issued a report on Postgraduate Education (House of Commons Paper No. 96). The general thrust of the document was that growth in postgraduate education had been insufficiently controlled, that postgraduate education should be shaped less by student demand and more by the needs of the economy and society as a whole, and that there should be a major change of emphasis towards postgraduate education being for those who had already experienced the world outside university. We thought at the time that it was a poor report as far as it applied to the PhD, and now that the House of Commons has just got round to debating it, we still think it's a poor report.

Much play was made, during the short debate, of the lack of any formal response by the Department of Education and Science to the document. By way of explanation the Under-Secretary (Miss Joan Lestor) pointed out, rather apologetically, that a large number of bodies were interested and it took time to collect and consider their views. Since the report is a potential threat to the whole way of doing academic research and since the bodies with an interest all have their offices within a bus-ride of the department one wonders why the delay in standing up for the PhD—could it be that the department is in broad agreement with the report? Miss Lestor's opaque speech gave no clues.

Mercifully, at the very end of the debate, one member, Dr Jeremy Bray, was prepared to stand up and plead for more understanding of the basic purposes of postgraduate education. "We need a permeation of the attack on the problems of modern society by the robustness, objectivity, and the exposure to the test of experience, which is the characteristic of good research. Any activity which fosters that and which seeks to spread those qualities within our society should not be lightly brushed aside." An unashamedly Popperian viewpoint probably lost on the House which immediately went on to discuss police recruitment.

The PhD degree is a relatively easy target to attack because its recipients do not seem to confer on society the same sort of benefits as, say, medical doctors. More recycle into the educational system than go elsewhere (not that industry, commerce and the Civil Service wants them all that much). Many get their degree and then seem to throw it all away by going on to do something apparently totally unrelated—an offence which is widely practised, indeed encouraged, after 16 years of education but totally unacceptable after 19. And they are alleged to be strangely unresponsive to society's needs, although they are invariably supervised and guided by more senior people.

What ought to be more widely known is that at least as far as the research student is concerned the transition from undergraduate to postgraduate work is such a change in style that few of those who drift into research for fear (as Mr Neil Marten put it) of the outside world survive long. To switch from a situation in which every problem has an answer (and preferably one that can be written down in a couple of sheets of examination paper) to a situation in which one is not even sure that the problem is worth asking, let alone whether it is answerable, is to expose oneself to a new and often icy world. And if it is done at all, it must be done young. The record of those who do come back for a research degree after several years in, say, industry does not make a compelling case for the post experience grant.

Many take the PhD degree but do not then seem to capitalise on it; this is easily seen as waste, and no doubt the Expenditure Committee could see it as that, but substantial numbers of students realistically face the fact that after three years of conducting research they are not cut out for a lifetime of it. In those three years, though, they will have learnt a whole new philosophy and methodology (and learnt by experience, not instruction). There are other places where such experience is needed than in the laboratory.

Finally, what should shape postgraduate education—the needs of the economy and society or student demand? The committee leaned to the former and there is much to be said for manpower planning in higher education. But society is generally only capable of servicing its present needs, and somewhere there has to be some very careful thinking about what the community will need thirty years hence. The future of a technological society is at least partly in the hands of the emerging student; to deny him the right to choose what sort of society he wants to work for is to try and prevent the further evolution of society—however reasonable the arguments on the other side may seem. □

Seeds of hope

The improved varieties of staple crops which hold out the eventual hope of feeding the world's growing population, will depend for some of their most valuable characteristics on the genetic raw material contained in the old indigenous varieties of crops cultivated by peasant farmers for thousands of years. But this pool of inherited variation is rapidly drying up because of the success of the very varieties it helped to create. The primitive 'landraces' and their wild relatives have in the past proved an invaluable source of resistance (worth many millions of pounds) to serious pests and diseases, and have provided genes for many other desirable characters such as improved nutritional quality and adaptations to drought or cold. The serious implications of the rapid disappearance of this reservoir of valuable genes is now recognised in many quarters, and work to conserve the variation which remains is under way throughout the world. Eleanor Lawrence reports on one of the first institutes specifically set up to tackle this problem as it enters its second decade.

THE Genetic Resources Unit established by the FAO within the Aegean Regional Agricultural Research Institute (ARARI) just outside Izmir, on Turkey's Aegean coast, started life in 1964 as an experiment unique at the time. It was the first such unit specifically set up to deal with the collection, storage and evaluation of the rapidly vanishing genetic variation in cultivated crops within a region holding a large part of the remaining stocks of primitive cultivars and wild relatives of some of the most important temperate crops —wheat, barley and grain and forage legumes.

The concept of a 'gene bank' itself was hardly new even in the early 1960s. Plant breeders had collected useful material from all over the world to incorporate into plant breeding trials, but material not of immediate use had often been discarded. Large reference collections of seed of important crops were held at the National Seed Storage Laboratory at Fort Collins in Colorado, and in the USSR, where the now irreplaceable collections made by N. I. Vavilov and his coworkers in the 1920s and '30s were kept in Leningrad and at other centres throughout the country. Collections of various types and sizes were also held throughout the world.
But there were as yet no medium-sized institutes, actually located in the countries where the greatest genetic diversity occurred, which had as their primary aim the systematic collection, and on-the-spot conservation and study, of valuable seed material, with the additional aim of screening and describing the material and making it freely accessible.

The importance of the Near East (stretching from Turkey to Pakistan in the east and Lebanon in the south) as a centre of diversity for many temperate crops stems from its complex geography and its long continuous history of agriculture. The Near East is the cradle of modern 'western' agriculture, based on wheat and barley as staples, which were first cultivated there some 10,000 years ago. Archaeological evidence shows that a mixed agriculture based on wheat and barley had developed throughout the region by the 8th century BC. Barley, emmer wheat (tetraploid *Triticum dicoccum*, a relative of the modern *durum* wheats), the modern hexaploid bread wheats (*T. aestivum*) and the diploid einkorn wheat (*T. monococcum*), still cultivated in parts of Turkey today, have all been found at archaeological sites dated between 6000 and 7000 BC.

But today, according to a survey carried out by FAO and the International Biological Programme published in 1973, improved varieties of both *durum* and *aestivum* wheat have very nearly replaced local cultivars except for remnants in the more remote regions. The wild progenitors of both wheat and barley can still be found and are even increasing in localities where they happen to be within protected 'national park' areas. Today wild barley flourishes in the ruins of Ephesus.

If this gene pool of inherited variation built up over thousands of years of evolution, selection and diversification into a wide range of habitats, is allowed to disappear completely, the plant breeder's ability to respond to a changing world situation will be severely restricted. These traditional 'landraces' and their wild relatives are often the only source of resistance genes to a wide variety of serious pests and diseases, such as stem rust in wheat. The old landraces are sometimes not very productive, and some do not respond to fertiliser treatment, but locally adapted populations can withstand conditions of drought or cold for instance which would soon lay low most modern varieties. These characteristics are needed to incorporate into breeding programmes with the generally more productive, modern varieties. Also, with fertilisers and pesticides growing more expensive each year, modern varieties which depend for their high yield on generous inputs of fertilisers may become less attractive. Traditional cultivars which produce good yields under less favourable conditions may prove a more rational basis for future breeding programmes
Harvest in Turkey: reservoir of genetic resources

for some areas.

In the decades since the Second World War, Turkey has seen widespread changes in agricultural practice. Changes in land use, introduction of improved varieties and modern methods of agriculture including the use of herbicides for weed clearance, have hastened the disappearance of the old locally-adapted populations.

In 1961, the Turkish government asked for international aid to research into problems posed by the changeover to modern systems of agriculture. In 1963 the United Nations Special Fund (now incorporated into the UN Development Programme) allocated funds and with FAO as the executive agency the 'Izmir Project' began. The Turkish request for aid coincided with FAO's own wish to establish a centre for the collection, study and distribution of forage legumes and grasses, and also with a growing consciousness of the urgent need to survey and collect rapidly disappearing germplasm of important crops. Over the nine years during which the project was financed by UNSF/UNDP, the Turkish government provided a total of $980,000 worth of land and staff salaries plus $110,000 in cash, and the UN around $1,290,000.

The original aim was to establish a Crop Research and Plant Introduction Centre, which as well as carrying out genetic resource surveys and conservation would maintain and initiate breeding programmes and also serve as the point of introduction for new varieties entering the country from abroad. The introduction of plant material from another country is always a risky operation because of the possibility of disease being brought in accidentally. Quarantine procedures for screening incoming material and certifying outgoing seed as disease free are an important part of the work of any centre involved with the distribution of plant material. It was also essential for a unit concerned with genetic resource conservation to keep a finger on the pulse of plant introduction so that they could foresee when the introduction of new varieties into previously undeveloped areas might threaten valuable sources of primitive cultivars.

But the early days of the project were dogged by organisational problems. At the time of its establishment, the Turkish government was also in the process of setting up its own agricultural research institute on the same site using the same funds and facilities provided for the FAO/UNSF programme. It proved logistically impossible to keep the two elements separate, and the original interpretation of the project by FAO as being one primarily of building an institute with an essentially international outlook for the collection, conservation and use of crop genetic resources became to some extent engulfed in the Turkish aim of building an institute of much wider and more immediate value to Turkish agriculture. This was recognised in a merger with the Ministry of Agriculture institute, the present ARARI, in 1967 and the present status of the genetic resources unit within ARARI. From 1970 until UNDP ended its financial aid in 1973, all UNDP/FAO funds were concentrated on the development of this discrete unit within the institute.

The original programme also proved to be overambitious given the limited financial resources and organisational difficulties. The present efficient and streamlined genetic resources unit has, for the time being, had to discard its original plans for full evaluation of the material collected and now concentrates on collection, storage, and computer documentation of the extensive herbarium and seed collections.

Since 1968, there has been a systematic collecting programme in crops particularly endangered by the changing patterns of agriculture. More than 2,600 samples of cereals, 3,759 samples of grain and forage legumes, 615 samples of vegetable and spice crops and 1,513 samples of 'industrial' crops (including over a thousand samples of opium poppy seeds) have been collected from all over Turkey; additional accessions have been received from other countries, and deposited in the excellent cold storage facilities completed in 1968.

The poppy seed collections were made in 1972, under the impending ban on opium poppy cultivation. No collections had been made previously so when the government ban was announced an emergency collection of seed stocks was mounted. Although FAO does not condone the traffic in opium, *Papaver somniferum* and *P. bracteum* are also important oil seed crops in more than 2,000 villages in Central Anatolia and it was hoped that varieties with high oil content and low morphine content could be selected for restocking. With the full cooperation of the government, local agricultural extension staff were quickly trained in the basic techniques of collecting and over 1,000 samples were gathered in the one season before cultivation stopped.

This exercise also proved an excellent example of the greater efficiency of collections organised and carried out by trained local staff, familiar with the terrain, language and customs of the country. The one-off expeditions mounted by foreign teams, unfamiliar with country and language can sometimes prove unproductive, and one of the roles of the Izmir centre has been to provide support and advice for the many expeditions which visit Turkey, attracted by the diversity of its natural and cultivated flora.

A survey and collection of the wild and traditional varieties of fruit and nut trees, such as almond, walnut, apple and peach, which were first cultivated in the Near East and grow wild in Turkey, has also been made. Although these are not staple crops, they are particularly vulnerable to changing land usage. The traditional mixed orchards where the old cultivars are grown are not being replaced, and large commercial plantations of new varieties are being planted instead. The wild species are also disappearing rapidly. Unlike herbaceous plants, tree germplasm is often difficult to conserve

as seed. A living collection assembled at Izmir was finally abandoned when it proved too difficult to maintain and evaluate the living trees in conditions far removed from those to which they were adapted, and attention was instead concentrated on selecting the best lines as a basis for varietal improvement. *In situ* preservation in protected areas probably gives the best chance of preserving the wild varieties.

The ending of UNDP aid in 1973 marked another change in emphasis for the Izmir centre. Since 1970 the international contributions had gone solely to the genetic resource unit, and this now continues with funds from the Swedish International Development Authority through FAO, which have been promised until mid-1976. At the same time, the scope of the genetic resource project was formally widened to take in the neighbouring countries of Syria, Iraq, Iran, Afghanistan and Pakistan, under the title of the Near East Project, which has now been in progress for one year, and aims, with Izmir as a focal point, to coordinate the national efforts in these countries, all important areas of genetic diversity.

The future role of Izmir as the main regional centre is now in some doubt, however, despite its excellent technical facilities, scientific record and core of highly trained, experienced Turkish staff. The problems arise from its present position within a government-controlled institute, where although funded internationally, it is still under the ultimate control of the director of the ARARI, and therefore not completely independent.

Financial support for the Near East Project after mid-1976 is to be channelled through the newly-established International Board for Plant Genetic Resources (IBPGR) which is considering an alternative for the regional centre to serve this programme. In the present reappraisal of world-wide genetic resource conservation at present being carried out by the IBPGR with a view to linking existing programmes into a global network, it would prefer where possible that the regional centres be autonomous and be able to take a truly international view of their essential function of making the seeds they collect and store freely available. The Consultative Group on International Agricultural Research, the parent body of the IBPGR, is setting up a new international agricultural research centre to serve the Near and Middle East in the Lebanon and this might prove a satisfactory location for the regional centre for genetic resource conservation as well, with Izmir continuing as a national centre —perhaps under international funding if necessary.

The Izmir project was a milestone in

Distribution of seed samples

	Turkey	Abroad	Total
1967	2,975	160	3,230
1968	214	2,624	3,214
1969	1,473	265	3,214
1970	3,668	195	1,738
1971	3,474	1,672	5,146
1972	2,186	976	3,062
1973	447	1,578	2,025

Over the years samples of about 75% of the collections have been sent overseas to scientists and plant breeders on request, with the greatest demand being for wheat, barley and grain legumes. Complete duplicate collections of the cereals have been sent to Canada, chickpeas to India, Holland and the Lebanon, lentils to Argentina and the Lebanon and broad beans to Sweden, East Germany, the United States and Australia. When seeds are sent they are always accompanied by requests that any information on performance and characteristics be returned so that records can be kept up to date.

the transition of genetic resource conservation from a state of individual effort into an internationally coordinated effort, but like many pioneer projects is now hampered by limitations imposed by its origin at a time when the problems of organising genetic resource work on such a scale were imperfectly appreciated.

Another candidate which has been put forward as an alternative regional centre is Ege University near Izmir.

There would be many advantages in locating a centre at Ege, which already has a good department of agriculture, existing collections and facilities including cold storage. Future work on genetic resources, once the initial urgent need for collection has been satisfied, can be usefully diversified into basic research in plant genetics, taxonomy, pathology and ecology which will illuminate the potential of the collected material for use in plant breeding programmes. The present FAO Project Officer feels that two projects especially would be particularly appropriate. As legumes always grow naturally in a symbiotic association with nitrogen-fixing rhizobia, which are specific for different species and probably as genetically variable as their plant hosts, a gene bank of rhizobia complementary to the legumes seems essential for the conservation of the natural symbiotic system, and would also prove invaluable for bacterial geneticists who are now trying to breed more efficient strains of rhizobia and attempting to extend their host range. The UN Environment Programme is considering plans at present for the international coordination of *Rhizobium* collections.

Such a centre would also be an ideal base for work in the variation found between different races of plant pathogenic fungi, which poses a problem for the breeder trying to incorporate resistance into the plant, and for surveys of the extent of disease resistance within areas where it has arisen naturally.

A completely new regional genetic resource centre, wherever it is eventually located, will, however, take some time to put into commission and time is in short supply as far as exploration and collection are concerned. The facilities at Izmir will certainly be needed more than ever in the next year or so. Most of the Near East countries have vigorous programmes of agricultural improvement, which within the next decade will further reduce the areas where the older varieties still remain.

Other changes in the Near East Project may be envisaged under future IBPGR funding. The anomalous position of the oil producers Iran and Iraq as recipients of international aid is unlikely to continue. Although the international organisations will be happy to provide expert help and training facilities for young scientists, it is hoped that Iran and Iraq can be persuaded to become contributors along with the other donor countries which comprise mainly the industrialised nations. Although scientists within these countries are fully aware of the necessity to conserve their remaining sources of variation in cultivated crops, it is sometimes difficult to persuade governments that such essentially long term projects should be supported. But the Izmir Project showed that for a comparatively modest sum, compared with the thousands of millions of dollars often spent on prestige technology, irreplaceable sources of variation can be safely banked for the future. □

international news

(MOS)MOSCOW,July 15 (AP)-Muscovites watch televised program Tuesday from Soviet Baikonur space center. Shown on screen is Alexei Leonov, commander of Soyuz space-ship as he enters Soyuz.(AP WIRE-PHOTO) (dm/stf/BY) 1975

THE Apollo-Soyuz link-up has undoubtedly proved a salutary exercise in the logistics and diplomacy of international scientific cooperation, and as such has merited not only congratulatory speeches from Messrs Ford and Brezhnev, but also a special commemorative perfume EPAS (Experimental Project Apollo Soyuz, bottles by Revlon, contents by Novaya Zarya) distilled in honour of the occasion. But while the politicians, planners, translators, coordinators and language instructors congratulate themselves on a well-earned triumph, the question remains: what precisely did the joint mission achieve in the scientific field which could not have been accomplished by individual national missions?

Of the "international" experiments carried out by the mission, the artificial solar eclipse made by undocking the two craft, and manoeuvering them into a position in which the Sun was eclipsed by Apollo, and the corona photographed from Soyuz could, theoretically have been effected by two spacecraft of the same "nationality".

The unilateral experiments, *a forteriori*, are likewise independent of the joint nature of the mission. Their juxtaposition in a joint mission does, however, stress a slightly more exotic trend from the American side since in

Sweet smell of success

from Vera Rich

contrast to the fairly routine astrophysical, geographical and biological experiments of the Russians (photography of the zodiacal light, investigation of refraction and transparency of the upper atmosphere, the study of the effect of weightlessness and other conditions of spaceflight on fish embryos and micro-organisms), the American programme included the growing of crystals, the production of lithium fluoride fibres, the casting of magnetic materials, and two electrophoresis experiments (one of West German origin) dealing with the separation of live cells and the isolation of enzymes. It must be remembered, of course, that this Soyuz flight is, from the Soviet point of view, simply a rather more spectacular member of a continuing series, whereas although NASA has two Apollo craft remaining in care and maintenance, there seems no likelihood that with current budgetary restrictions it will be able to launch them.

This, to a certain extent, vitiates the only practical purpose of the joint

mission. In a television interview, a high-ranking Soviet spokesman for the "Interkosmos" council for cooperation in space research stated that according to the International Space Treaty, the contracting parties are bound to implement all possible means to render mutual aid and assistance in the case of emergency. International ventures on perfecting means of docking and rendezvous will therefore continue. Moreover, he said, the future of space research lies in international space stations. The possibility of a Soviet space-craft coming to the aid of a U.S. craft in distress is clearly a tempting propect. The helplessness of the Soviet cosmonauts to effect a salvage operation in the case of the Apollo-13 near-disaster caused keen heart-searching among those who realized what a propaganda boost such a rescue would have been. In all events, unless the U.S. Congress will release the necessary funds, it seems unlikely that Soviet spacecraft will be able to practice the necessary rendezvous and docking manoeuvres, except on each other.

In an ideal future, without budgetary restrictions, where international teams can work together in manned space stations, or even interplanetary flights one outcome of the current

KUBASOV
LEONOV
STAFFORD
SLAYTON

Apollo Soyuz mission will have to be borne in mind—the increased physical stresses observed from the telemetered medical data. The crews were, of course, old for the task, and Slayton had a history of cardiac trouble, but age does not seem the only explanation. A number of factors may well be involved—the intense political significance with which the mission was loaded and the almost embarassingly detailed TV coverage. But these are factors which would with time, gradually fade as international flights became commonplace. It is possible, however, that the strain of operating in a bilingual situation, added to all the other in-flight stresses, may have

proved more wearing than expected. Perhaps therefore the most profitable follow-up of Apollo-Soyuz would be a detailed study of a multinational crew in a simulated long-term mission, with a similar but uninational crew as control experiment, in order to study in depth the additional stresses, if any, caused by international cooperation.

John Gribbin adds: If Apollo-Soyuz was anything more than a political stunt, it was an attempt to pave the way for future joint missions in space. The most glamorous manned mission of the foreseeable future (by the turn of the century) would be a visit to Mars, where the great cost would surely require a global, rather than any national, effort. But before then, and perhaps within five or six years, there is plenty of scope for significant cooperation in Earth orbit.

Curiously, the plans of Soviet and American space scientists dovetail together so well that, politics apart, they seem made for each other. In the best traditions of Tsiolkovski, the USSR is working towards a reasonably large permanent (or semi-permanent) manned space station—but they seem to be intending to build it with the aid

of what are now conventional rockets. On the other hand, the present US effort is towards a superb haulage vehicle for Earth orbit trips, the Shuttle. What could be more natural than to use the Shuttle as a means for supplying the space station of the 1980s?

NASA at least is already well aware of the needs for international collaboration on future projects, and perhaps the most significant single item to be carried by the Shuttle, the Space Laboratory, is being designed and built in Europe, as the European Space Agency's contribution to manned spaceflight. In the heady excitement of last Thursday's golden handshake, the dream of collaboration involving the US, USSR and Europe to fulfill science fiction predictions of permanent orbiting Earth stations semed almost to be a reality; in the more down to Earth days to come, it seems more likely that any such dreams will be blighted by the attitude (on both sides) typified by a remark attributed to one of the US astronauts to the effect that "I like the Russians we've worked with. But that doesn't mean I have to like their lousy system of government." □

A cooperative research programme between the USA and Egypt in the area of remote sensing applications to a national resources survey (in geology, agriculture groundwater and so on) was initiated in 1972 by a proposal submitted by Dr M. Abdel-Hady (an Egyptian scientist who is now Professor at Oklahoma State University, OSU), to the National Science Foundation (NSF) and the Egyptian Academy of Scientific Research.

The project was approved and funded by Oklahoma State University and the NSF for a three-year period ending in 1975, and Professor Abdel-Hady was granted research leave from OSU to direct the effort from Egypt.

The programme so far has covered work in the following areas:

● A geological, structural, drainage and mineral resources survey for the northern region of the Aswan Dam reservoir basin, comprising an area of 68,000 km² on both sides of the river.
● Infrared thermal imaging from aircraft over an extensive area south-west of Cairo. From this investigation, in a typical arid climate, lithological anomalies were significant in demonstrating the role of remote sensing techniques in the discovery of important economic minerals.
● Several studies of the use of remote sensing techniques for the survey and early detection of fungus and nematode diseases in regions of Egypt where important economic crops are grown.

● Geological, water resources, potential oil, mineral resources, and structural maps of the Sinai Peninsula from ERTS-1 Satellite images (under contract with the Ministry of Reconstruction and Housing in Egypt).
● Thermal (infrared), magnetic, radiometric and multispectral photographic aircraft surveys over the entire Suez

---

from Salah Galal, Cairo

Canal Zone, to provile basic surface and subsurface geological maps for a strip 20 km wide, along the entire length of the canal to assist the redevelopment and reconstruction projects in this area and to provide data about the subsurface to the international construction companies in charge of designing the proposed tunnels under the canal.

Several other investigations dealing with agriculture, land reclamation, mineral resources, groundwater and the environment are now proceeding, and more than 10 technical reports and research papers are being prepared from the results of these investigations. These will include studies of the Suez Canal zone (surface and subsurface geological and groundwater survey); the north-west coastal region of Egypt (geological and soil survey, groundwater survey, soil salinity, and agricultural

survey); and the Salheia Project (10,000 km² between the Nile Delta and the Suez Canal). In this project a regional and detailed geological, soil hydrological and crop survey is being carried out, with the aim of reclaiming 10.000 acres of land.

Other projects now being negotiated include a crop survey inventory and early detection of some nematode and fungus diseases in major economic crops in Egypt; a survey of iron ore deposits over large areas of the Western Desert; a regional geological soil and water resources survey for 100.000 km² west of Aswan; and a regional geological, structural and petroleum and mineral resources survey of a large area in the Western and Eastern Deserts of Egypt.

Regional groundwater investigations and mapping of groundwater reservoirs are planned for the Nubian Sandstone in Egypt, northern Sudan and Libya, and regional and general area reconnaissance will take place in the El-Sudd region in Sudan for the planning and location of the Jongoli Canalisation Project (an important water resources and water conservation project planned jointly by the governments of Egypt and Sudan). Cooperation in carrying out this investigation by satellite image interpretation and by means of aircraft is now being negotiated with representatives of Egypt and Sudan at the Higher Commission for the Upper Nile Waters, Ministry of Irrigation.

Brazil and Germany do a nuclear deal

from Ian Bridges, Bonn

IN Bonn at the end of June foreign ministers Hans-Dietrich Genscher of the Federal German Republic and Antonio Azeredó da Silveira put their signatures to an epoch-making treaty. Under its terms the two countries are to develop, using German know-how and Brazilian capital and uranium, a complete nuclear fuel cycle, from mining to waste disposal. This was the German's first breakthrough in the complex game of world-scale technological and commercial diplomacy. The range of reactions to the deal is a reflection of the many and diverse planes on which it will have an impact. Within Germany, the accent was put on the value of the commercial contracts and their spin-off in balance of payments terms. In Brazil, relief at ensuring energy supplies for the future, when hydroelectric power will have been stretched to its limits, mingles with satisfaction at an assertion of independence from Uncle Sam. In the United States, Congress echoed to expressions of high moral indignation that Germany, of all countries, should have given the Brazilians the wherewithal to "make the bomb"

Shrewder observers noted that the deal had long-term political and strategic implications, relieving the Federal Republic of dependence on US enriched uranium in the closing decades of the century. And in the background, ecologists lamented that it opened the way to a further spread of nuclear power, with potentially disastrous implications for the future of mankind, whilst scientists speculated about this as a test case for the effectiveness of control over the peaceful use of a new enrichment method.

Technically, the nuclear complex that is to be built at Angra dos Rios, on the Itaorna Bay 130 miles of Rio de Janeiro, represents a double first. It is the first complete nuclear power cycle to have been sold. This indeed was the key selling point with the Brazilian government, who could not obtain a similar offer from Westinghouse, whose single 600 MW standard plant is currently being built within a few hundred yards of the site for the new complex.

By the time the cycle is completed (within 10 years), it will cover prospecting for and mining of uranium within Brazil, which is known to have such resources; a uranium enrichment plant; two completed 1,300 MW pressurised water reactors, with another six reactors on the way; a pilot plant for making reactor fuel elements, with a commercial plant to follow; and a

plant for processing used fuel. But in this list, one thing stands out—the enrichment plant. For this is the first commercial sale of the method known as nozzle or vertical wall centrifuge (German: *Trenndusen*). This has been developed by the Federal German nuclear research centre in Karlsruhe— and in parallel by the South Africans —but has not been used commercially so far.

It was mainly the ability to sell an enrichment process—plus their proven engineering ability across the whole field—which gave the Germans the edge over the Americans Brazil's economic planners had begun to find themselves doubly squeezed on the energy front With maximum exploitation of the country's considerable hydroelectric power resources already foreseeable, they had made the switch to oil when the world oil crisis hit them. For a country which had just begun to master about the worst runaway inflation rate in the world, this was a shock. But thinking in terms of nuclear power as a medium-term alternative, they ran into the hard fact of the predicted enriched uranium shortage, already making itself felt, and due to be worse at the end of the 1980s. So the nuclear choice looked like restoring a dependence on the US which they were trying to break.

The answer was to develop a full fuel cycle. enriching their own uranium. But the gaseous diffusion method, the only one the US companies could theoretically have provided, could not be made available on non-proliferation grounds, because it can be used to enrich up to the levels needed for military uses. The Anglo-German–Dutch centrifuge method is also subject to the tightest restrictions, under the secret clauses of a deal with the United States, and is in any case not yet available commercially. The German method, on which the scientists in Karlsruhe have concentrated, is generally recognised as being "proliferation safe"—meaning that it can only effectively be used to enrich up to the low levels, 3 5% or so, needed for peaceful uses. It seems that any adaptation of the vast installations to achieve higher levels, would be so easily controlled.
costly and so conspicuous as to be

In these circumstances, the wave of protest in the US Congress against the German–Brazilian deal, specifically on the grounds that it meant "giving the Brazilians the bomb", seems hard to explain, unless resulting from inadequate technical knowledge. Although Brazil is not a signatory of the non-proliferation treaty, the Germans made it a condition of the sale that Brazil should accept controls by the International Atomic Energy Agency

in Vienna. The powerful pressure which the US government also tried to put on the Federal Republic, against the deal, seemed to be more general. But as the Germans tended to point out, if the danger foreseen was that plutonium from the reactors, after their first period of operation, was seen as giving Brazil a military potential, this is a danger equally present in US sales of reactors to countries at least as potentially dangerous as Brazil, such as Iran or Egypt.

One expert has suggested a third possibility: one of the inventors of the centrifuge spent many years after the War, when working on the project, in Brazil before returning to Germany, and it would thus be surprising, said this source, if the Brazilians had not discreetly gone on with the centrifuge; but this was queried by others who pointed out that the bottleneck in centrifuge development was not the invention itself but the difficult high-temperature technology of the bearings, something the Brazilians are not equipped to master. In short, if Brazil is suspect as a potential maker of bombs, the breakthrough is going to come anyway As for innuendoes that the deal also gives the Germans the potential of developing a bomb together with the Brazilians, there seems no foundation for them—at least as long as the Federal Republic retains its present political balance.

From the Federal German point of view, in any case, there is no doubt that the Brazilian deal was pushed through essentially for its commercial value. For the Germans it was a lucky break when they were beginning to despair of ending the Americans' domination of the world market for nuclear technology and engineering. An estimated 15,000 million DM of public money has been poured into the nuclear industry, which is now geared up to produce and sell reactors commercially. Kraftwerk Union AG, joint subsidiary of Siemens and AEG (though AEG are currently selling out) can produce and sell six reactors a year Given a six-year construction cycle, this means a potential of 36 contracts running in parallel. Currently, there are orders for only 17. Except in neighbouring countries—Austria, Switzerland, Holland—KWU has almost lost out to Westinghouse or General Electric—not least because of the all-out diplomatic back-up enjoyed by the Americans. Thus the Germans recently won an order from the Shah of Persia for two reactors—only to see the Americans carry off a contract shortly afterwards for a programme of eight over a 10-year period.

In Brazil, precisely the reverse has happened. The starting-point was a straight bi-lateral inter-governmental

pact, signed in 1969, on the exchange of scientific information. From the start the Brazilians showed the most interest in the nuclear sector, and soon talked about a full fuel cycle, but were not taken seriously. In 1972 the Germans made a bid for the reactors the Brazilians had decided on, but when they saw Westinghouse carry off the first contract they almost gave up. Then, in the spring of 1974, came a request for the full fuel cycle, this time serious. The talks, on which German industry was brought in, were kept secret for a long time.

When it did come out, in the early summer, the news was an enormous fillip for a German economy reeling under bad news. For years, the prosperity of the Federal Republic had been export-led, with booming sales of investment goods abroad balancing out the staid performance of private consumption within the country. In 1975 exports had begun to flag, reflecting the recessions elsewhere in the industrialised world. Of the investment in the nuclear programme planned with the Brazilians, an estimated 12,000 million DM was to be spent in the Federal Republic over 15 years. There was guaranteed work for the 13,000 strong skilled workforce at KWU, plus sub-contracting to 300 or more firms for 80% of the material to be used. But there can be no doubt that nuclear development proper will spearhead a wider commercial breakthrough. There will clearly be a need for steel produced on the spot, and for a range of engineering firms; and around this tremendous source of electric power, fertiliser and chemical plant will proliferate.

Far more than was generally realised at first, the Federal Republic and Brazil have gone into partnership in the business not just of producing nuclear power, but of supplying the kits for others to do the same. The briefest summary of the full range of cooperation arrangements illustrates this.

● a joint company has been set up to carry out prospecting and mining of uranium. A Brazilian state company, Nuclebras, has 51% and Germany's Uran Gesellschaft the other 49%.

● the same Nuclebras will take part in developing the vertical wall enrichment plant, which will be built jointly in Brazil by Steag and Interatom.

● KWU and the specialised company RBU are to build first a pilot plant and then a commercial one for making nuclear fuel elements for Brazilian reactors; and significantly Nuclebras will have 70% and KWU 30% in a separate company set up to market fuel elements.

● for re-treatment of nuclear fuel, Nuclebras will have two German firms

THAT much-publicised proposal to reestablish a science policy office in the White House, announced by President Ford in May, is making glacial progress through Congress, and it now seems certain that the new arrangement will not be in place until late autumn. That would be too late for the office to play much part in deliberations on the 1977 budget and, with the Presidential elections by then in full swing, it may be difficult to persuade a top flight person to head the office for what could be a short stint.

The House Committee on Science and Technology, which is dealing with the proposal in the House, completed hearings on the measure last month, and it is not likely to take any formal action until after Congress returns from its August recess. In the Senate, meanwhile, the proposal has been referred to three different committees, and joint hearings are being planned for September. Congressional staff members concerned with the legislation suggest that it will be at least October before a bill is passed and sent to President Ford.

Ford's proposal, which was formally spelled out in a bill sent to Congress early in June, would establish a small office consisting of about 15 people—a number which was "pulled out of the air", according to testimony given by Vice-president Rockefeller—and a budget of about $1–1.5 million a year. Although it would be concerned chiefly with helping to formulate Administration policy on non-military science and technology, the office would play a rôle in military matters "when asked".

Congress is likely to give Ford

pretty much what he asked for, although it is likely to stipulate that the head of the office, who will bear the title of Science Adviser to the President, should be approved by the Senate before he is officially appointed. It is also possible that Congress will spell out the office's areas of responsibility in some detail, particularly in regard to its rôle in military science policy making.

During the House Science and Technology Committee's hearings, the proposal was warmly endorsed by several prominent scientists who had long been protesting former President Nixon's decision, in January, 1973, to scrap the White House science policy arrangements established by President Eisenhower. Having persuaded President Ford to reverse his predecessor's decision, however, the proposal's supporters have won only half the battle—the other half is to ensure that the arrangement is used effectively when it is in place, and that may be more difficult.

● Echoing warnings issued in a recent report of a committee of the National Academy of Sciences, the Geological Survey, which is part of the Department of Interior, pointed out last week that the United States is becoming increasingly dependent on imports of several important minerals. The survey urged that a national policy aimed at conserving scarce minerals and substituting others in some uses, should be adopted. By the year 2000, the Geological Survey predicts that the United States will be completely dependent on imports for 12 commodities, more than 75% dependent on imports for another 19, and more than 50% dependent on imports for a further 26 commodities.

acting as partners: KEWA and UHDE.

● only the first two reactors of the eight planned are to be delivered on a turnkey basis by KWU, with work starting on one in 1976 and the other in 1978. Nuclebras and KWU are going 75–25 in a nuclear engineering company, while the Austrian firm Voest takes part in a nuclear components company.

If there is thus a vast commercial pay-off for the Federal Republic, there is also a longer-term advantage of capital importance. The Federal Republic will have guaranteed access to uranium—and a guaranteed source of enriched uranium just at the time the squeeze starts operating. This means escaping from the present dilemma of having to rely on either the USA or the Soviet Union to provide the enriched uranium. The uncertainties of this were underlined earlier this year

when supplies to the European Community were halted without warning or consultation, formally because of inadequate security. US pressures on economically sensitive areas like this are ill-received even by such loyal "Atlantic" partners as chancellor Helmut Schmidt—and the calls on the Federal Republic to drop the Brazilian deal tended to confirm the suspicions of those who had opposed German signature of the Non-Proliferation Treaty on the grounds that it would be used by US interests to hinder the Germans on world markets.

Thus the German-Brazilian deal is another step towards a changed pattern of world influence in terms of economic, commercial and technological weight and independence. The strongest of the western European industrial countries has linked hands with the country which is potentially a "first-league" member. □

Plant history in the Soviet Union

from Vera Rich

THE meeting of the Twelfth International Botanical Congress, which opened in Leningrad on July 6, has yielded a number of interesting reports from Russian botanists. In the field of palaeobotany, Leningrad palaeobotanist Boris Timofeev reported finding fossils of unicellular plant life in a 6-km core sample taken from the Ukrainian shield. This find, he claims, should be dated at 2,000 million years BP. It was also stated that this discovery will be important in the dating of strata of ancient rock, and that it will be of particular importance in oil and gas prospecting—though this claim seems somewhat obscure, since fuel deposits are conventionally attributed to the Carboniferous and not the Palaeozoic Period.

Also in the field of dating, a team of biologists and archaeologists have developed a "unified dendrochronological scale" for estimating climatic changes in the last 1,200 years More than 8,000 specimens of wood (mostly pine and fir) were used, from the surviving remnants of bulwarks, fortresses, log-built palaces, water conduits and the wooden pavements which were a notable feature of a number of major cities of the state of ancient Rus', notably Novgorod. A reliable time scale for eastern Slavonic history begins only in 988 AD with the conversion to Christianity of the Principality of Kiev, and the exact claim that the most ancient logs used (from sites at Pskov) date back to 770 AD shows rather too great an apparent precision. Equally puzzling is the claim that the data collected not only refer the growth of trees to the general picture of climatic change, but also to "events of cosmic origin". In particular, retarded tree growth is said to be correlated with chronological data on the flares of supernovae, intense meteorite showers and "dimness" of the Sun. This, however, raises the problem of how the original dating is arrived at Although presumably certain wood specimens can be clearly attributed to the dateable destruction of a given city (and in at least one case, the sack of Novgorod by Vseslav "the Wizard" in 1066, there is an exact coincidence with a cosmological phenomenon—the appearance of Halley's comet), the question how long the wood had been in use when destroyed remains open. If the dating involved is simply carbon-14 measurements, then the margin of error is surely too great to effect a definite correlation to a definite historical event. One suspects that, at some point, some circular argument has entered into the discussion.

Meanwhile, in the field of modern botany, an engineering team reports the development and use of "climatrons"—artificial climate machines with special light bulbs to stimulate different spectra of solar radiation, and special humidity and heat control systems, which provide a short cut to the evolution of new varieties of cultivated plants.

One such new variety (whether evolved in a climatron or not is unclear) is the splendid grass reported by Alexsandr Fedorov, which is intended as the cattle feed of the future and which grows to a height of some 5 m. In his message of greetings to the conference, Mr Kosygin, Chairman of the Council of Ministers of the USSR, expressed his view that on botany, "to a considerable degree, are based achievements in many branches of practical human activity, including agriculture " Certainly, at first glance, the 5 m grass must rank as such an achievement. Presumably it is intended for silage, rather than direct grazing Even so, the practical problems involved in its production on a commercial scale may well prove somewhat of an embarrassment to stock rearers, haymakers and the manufacturers of agricultural machinery.

● THE grainlands of the Steppe have been a potential cause of political tension throughout their history—indeed, there are those who would attribute the underlying cause of the Trojan war to the need of the Greek tribes to break through the Trojan blockade of the Dardanelles to the wheatlands north of the Euxine The nineteenth century brought, in Britain, the vexed issues of the corn laws and free trade, both of which assumed an inexhaustible source of wheat in the then Russian empire. In the twentieth century, Hitler envisaged an annexed Ukraine as the breadbasket of his Thousand-Year Reich, relying, presumably on the traditional picture of its fertility, rather than on the events of recent history For, under Soviet rule, grain production has consistently failed to reach the

planned target figures, and, in spite of the great drive to open up the virgin lands of Siberia to the plough, Soviet agriculture is no longer able to satisfy its home market, and this year, once again, must buy some 10 million tons of grain from abroad.

According to the Soviet press, most of the blame is to be placed on administrative difficulties—farmers so busy with paperwork on crop returns that they have no time to go about their primary business of cultivating and harvesting, machines standing idle for lack of spare parts or maintenance, or the occasional "wrecker" (a recent issue of *Pravda* reports that collective farmers not infrequently feed loaves of intended for human consumption to the livestock which they are allowed to tend as their personal property in their spare time). This is, however, a relatively easy solution to offer. The real situation, however, is more complex, and involves not only misapplication of the administrative process, but the whole Soviet system of planned agriculture.

In spite of the division of the Soviet Union into Union and Autonomous Republics, and (on a somewhat different basis) into economic regions, all planning in agriculture, as in all other types of production, originates in Moscow, and, it would seem, is often carried out with little regard for local conditions Stalin once, in speaking to Churchill about the "bad and difficult" time of collectivisation claimed as one of its advantages: "Not only have we vastly increased the food supply, but we have improved the quality of the grain beyond measure. All kinds of grain used to be grown. Now no one is allowed to sow any sort but the standard Soviet grain from one end of our country to the other."

Such a statement, of course, assumes that the "standard Soviet grain" is equally suitable for all the highly diverse habitats of one-sixth of the land surface of the Earth. In fact, a number of standard grain types have been developed for different conditions, and the claims made for them are impressive. A *Novosti* press release issued this year mentions eight valuable varieties of wheat developed at the Institute of Wheat Breeding and Seed Growing at Mironovka, south of Kiev, including, not only winter wheat, but an "insurance" type spring wheat "Mironovskaya-808" which can be used to supplement the grain balance when the winter wheat crop is damaged or frozen. This however raises the question, if winter wheat is at risk in a given area, why not concentrate on spring wheat altogether?

During the "maize craze" of the 1950s this crop was sown indiscriminately throughout the Soviet Union,

including areas such as Byelorussia where it could not be expected to ripen (Khrushchev suggested that in such areas unripe maize could be used as fodder). Even in more southern areas, the crop was introduced without proper arrangements being made for its harvesting, and on one occasion, when Khrushchev was to make a winter tour of Ukraine, the local organisers had no alternative but to flatten with large rollers the ungathered maize cobs that were protruding through the snow!

The ecological problems involved in such centralised planning may also be not fully understood The forestry conservation measures introduced in the Carpathians last May were intended not only to conserve the diminishing timber resources of the area, but also to restore the water-table of the agricultural areas of western Ukraine. The horizon-to-horizon culti-

vation of the virgin lands, without wind-breaks or chequering of fields, has led to considerable erosion.

Another problem is that of crop-rotation At the Twenty-Fourth Party Congress in 1971, the Minister of Agriculture, Vladimir Matskevich, stated that "correct" crop rotation had now been introduced on about 87% of arable land, but no details are available on the patterns of rotation involved. Unofficial reports, however, indicate a general tendency away from traditional patterns, and although the use of leguminous plants for nitrogen fixation is highly esteemed, it is chemical fertilisers that are seen as the basis of Soviet agriculture. In his report to the Twenty-Fourth Congress, Matskevich spoke of "mechanization, electrification and chemicalisation" as the basis for the intensification of agriculture, and "popular" articles appear in

the Soviet press on the advantages of chemical fertilisers.

From time to time, the Soviet press reports the triumph of small agricultural teams, working in virtually small-holding conditions, who have been able to increase the output of the land at their disposal by impressive percentages This can, of course, only be an experimental scheme—its large-scale implementation would undermine the basic theory of Soviet agriculture, collectivisation

● In the article *Soviet meetings, great and small* (*Nature*, **256**, July 17, 1975, page 160), paragraph 6 should have begun "The case of Dr Gluzman, whose incarceration in a prison camp seems to have been the direct result of his preparation of a report on psychiatric malpractice in the case of General Grigorenko, was raised at last year's Annual Meeting." □

IN these days of world-wide food shortages and rising food prices, it is hard to believe that a nation whose prairie provinces are often thought of as the breadbasket of the world neglects its agricultural and veterinary medicine schools. Yet that, according to the deans of Canada's 11 faculties of agriculture and veterinary medicine, is exactly what is happening

Through the Science Council of Canada, they recently published a statement saying the faculties "find themselves chronically underfinanced despite widespread government and public lip-service to the essential importance of food production and the need to apply education and research to its increase."

The "national statement" by the 11 deans went on to say the schools "lack funds for current activities other than teaching students; they do not have enough staff to achieve appropriately small class-sizes; and they have neither the time nor the money to undertake research that is needed and of which they are otherwise capable."

As a result, the deans declared, the faculties are intellectual resources that are being exploited to only a fraction of their potential.

It is not the first time the problems of science in agriculture in Canada have been made public Two previous Science Council publications identified a lack of coordination in research, particularly between the federal government and the universities (*Agricultural Science in Canada*, Background Study No 10, 1970; and *Two Blades of Grass*, Report No 12, 1971, Information Canada) Roger Gaudry, recently-retired chairman of the Council, also drew attention to the problems in his Annual Report for 1972–73.

Nor does the neglect of the agriculture and veterinary faculties mean that agricultural research *per se* is neglected in Canada. On the contrary, in 1972–73, Agriculture Canada (the federal government department) spent $90 million on research and development alone. But by contrast, the 11 agriculture and veterinary medicine faculties received total funding in that year of less than $50 million—only

---

Agricultural research at risk

from David Spurgeon, Ottawa

$15.5 million of which was for research.

And despite the inauguration in 1972 by the Ministry of State for Science and Technology of a "make-or-buy" policy—under which federal government departments were directed to contract out research where possible —Agriculture Canada remains the only department that spends about 99 per cent of its research budget in-house

The neglect of agricultural science lies chiefly in the small proportion of total R & D funds spent on agricultural research, and the lack of national planning, in addition to the over-emphasis on in-house governmental research.

"Out of about $1 5 billion a year spent on scientific and technological research in Canada, agriculture and its related sciences get much less than 10 per cent," says the dean's statement. "For want of staff or funds, needed research projects that promise high 'payoff' simply do not get started "

What makes the situation worse, they continued, is that what agricultural and food research is done is neither planned nor evaluated on a national scale in terms of its need and productivity.

Canada's three veterinary colleges have to turn away highly-qualified applicants for lack of space, the deans said The four Atlantic provinces together are rarely permitted to place more than six students a year at the only English-speaking institution in eastern Canada, the Ontario Veterinary College.

"The shortage of livestock veterinarians is a national problem for which every Canadian consumer is ultimately paying in increased meat prices."

In certain agricultural disciplines, professionals are also in short supply, to such an extent that government agencies have had to hire a significant proportion of their professional staffs outside Canada.

The deans' report was addressed primarily to the federal government, the provincial governments, and the food industries, according to Dr. Gaudry, who wrote the introduction But it obviously is hoped many ordinary Canadians will read it as well

It constitutes a direct challenge to the governments· "We can choose programmed ignorance and increasing risk in our food-production system, resulting from science policy by accident and a failure to understand the relationship between teaching, research and public service in the universities Or we can choose to develop a fully-articulated set of national agricultural policies and support strategies, in which each sector's distinctive advantages are used efficiently."

news and views

Microtubules and membrane topography

from Robert Shields

THE fluid-mosaic model of the cell membrane is rapidly attaining the status of the central dogma of membrane biology. Acording to this model (Singer and Nicholson, *Science*, **175**, 720; 1972) proteins are free to diffuse in the plane of the lipid membrane and assume random or homogeneous distributions over the cell surface.

More recently, evidence has been produced that suggests submembranous structures such as microtubules and microfilaments may also help to modulate the cell surface molecules.

When mouse B lymphocytes, which have immunoglobulin (Ig) molecules on their surfaces, are stained with fluorescent antibody to mouse immunoglobulin (anti-Ig), several patterns of fluorescence may be observed depending on the experimental conditions. If monovalent anti-Ig is used the cells are stained diffusely, suggesting a random distribution of Ig molecules over the cell. At low temperatures with divalent antibodies a patchy pattern of stain is seen implying partial aggregation of Ig molecules. When the temperature is raised the patches coalesce to form a fluorescent cap at one pole of the cell Patch and cap formation are not unique to lymphoid cells and quite a wide variety of cells including mouse fibroblasts have been successfully capped using anti-H₂ antibody (Edidin and Weiss, *Proc. natn. Acad. Sci U.S A.*, **69**, 2456; 1972).

The formation of patches is rather similar to the classical antigen–antibody reaction in solution in that it requires the antibody to be divalent and antigen to be present in multiple sites But the formation of caps is more complex than formation of patches, in that it is dependent on cellular metabolism, especially ATP synthesis. Patch formation is passive and depends on bivalent anti-Ig molecules collecting Igs by diffusion but several lines of evidence suggest that microtubules and microfilaments may play a part in the translocation of patches to form caps.

Perhaps the strongest evidence for the involvement of microtubules in the movement of cell surface proteins comes from work with the plant lectin concanavalin A (Con A) and B lymphocytes Native Con A is multivalent and

reacts with the α methyl-D-mannoside residues that form part of many of the glycoproteins of the cell surface. Con A acts as a kind of honorary antibody and at low doses will lead to capping of its receptors on B lymphocytes At high concentrations of Con A, however, no patching or capping is observed (Yahara and Edelman, *Proc. natn Acad Sci. U.S.A.*, **69**, 608; 1972). High doses of Con A inhibit not only the capping of Con A receptors but also the capping of Ig molecules with anti-Ig. If the cells are treated with colchicine or the temperature lowered to 4 °C, the cells washed free of excess Con A and the temperature shifted to 37 °C, caps will form.

An attractive explanation of these observations was provided by Yahara and Edelman (*Expl Cell Res.*, **91**, 125; 1975). They believe that molecules on the cell surface (such as Ig or Con A receptors) may exist in two interconvertible states, a free state where they are able to diffuse laterally in the lipid matrix, and a bound state where they interact directly or indirectly with microtubular structures inside the cell. Interaction of Con A with its receptors would lead to the binding of free receptors to a lattice of microtubules. The lattice, which is caused to form by high doses of Con A, also interacts with Ig molecules and prevents their diffusion to form a cap. When colchicine or other microtubule-disrupting agents are added, or the temperature is lowered (which also breaks up microtubules) the lattice would break up, allowing free diffusion of surface molecules and the formation of caps. But before this model for receptor modulation can be accepted other possible explanations of the results should be considered.

One possibility is that the binding of Con A to the lymphocytes induces a phase transition of the membrane and decreases the membrane fluidity This would inhibit the free translocation of Ig and other molecules in the lipid phase. Colchicine and vinblastin at the high doses used by Edelman could conceivably interact directly with the cell membrane increasing the membrane fluidity and permitting receptor movement. Lowering the temperature

might lead to phasing out of the cell membrane into fluid and non-fluid domains and so permit increased receptor movement (Petit and Edidin, *Science*, **184**, 1183; 1974).

These possibilities could be tested quite simply by using fluorescent lipid probes inserted into the cell membrane to measure membrane fluidity by fluorescent polarisation before and after Con A or colcemid treatment Although the evidence is rather sketchy it seems that binding of lectins to cells is more likely to increase than to decrease membrane fluidity (Toyoshima and Osawa, *J. biol Chem*, **250**, 1655; 1975) Furthermore lumi-colchicine, an isomer of colchicine which reacts equally well with plasma membranes (Stadler and Franks, *J. Cell. Biol.*, **60**, 297; 1974) but not with microtubules, fails to relieve the Con A-induced inhibition of Ig capping (Yahara and Edelman, *Nature*, **236**, 152; 1973). These experiments would seem to indicate that microtubules are involved in receptor movement.

A further possibility is that the binding of Con A to cells leads to the formation of aggregates on the cell surface that trap Ig molecules and so prevent their diffusion. Since there are about 1 4×10⁶ Con A receptors and about one thirtieth as many Ig molecules on the cell surface this is a possibility. To counter it, Edelman calculated that even at saturating doses of Con A, Con A receptor complexes occupy only 1 % of the cell surface and so are unlikely to interfere directly with the free diffusion of Ig molecules (Edelman *et al*, *Proc. natn. Acad. Sci. U.S A.*, **70**, 1442; 1973).

A related and more plausible possibility is that, since Con A will interact with many different glycoproteins through α methyl-D-mannoside residues, Con A may in fact directly crosslink Ig molecules at the cell surface. rather than through some submembranous microtubular structure This idea was given credence by the observation that Con A was able to cap Ig molecules without the need for anti-Ig Furthermore this co-capping takes place even in the presence of colchicine or at 4 °C, conditions that should disrupt microtubular structures. Con A also

induced co-capping of other molecules, such as the H-2 and Θ antigens in splenic lymphocytes, without recourse to use of the specific antibodies. In the light of these results it was vital to show that the Con A-induced inhibition of Ig motility was not an uninteresting artefact due to crosslinking at the cell surface but that microtubular structures were involved.

To do this Yahara and Edelman took advantage of the relative difference in size between the B lymphocyte and blood platelets (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 1579; 1975). They conjugated the small platelets with Con A and studied their interaction with splenic lymphocytes. The much larger lymphocytes could bind several of the platelets through the conjugated Con A, and the platelet distribution was random over the lymphocyte surface. The idea was to complex only a small proportion of the total Con A receptors of the lymphocytes and to see if Ig movement was still restricted. Staining the platelet-treated lymphocytes with fluorescent Con A revealed that only a fraction of the lymphocyte Con A receptors were bound to the platelets; furthermore the Con A receptors not bound by the platelets were distributed diffusely over the lymphocyte surface. The binding of more than ten platelets per cell was sufficient to prevent anti-Ig-induced capping of Ig molecules, showing that Ig redistribution was blocked by the occupation of only a fraction of the Con A receptors. When the lymphocytes with their bound platelets were treated with colchicine they showed polar or cap-like distribution of the platelets on their surfaces. But when these colchicine-treated cells were examined with fluorescent anti-Ig for the distribution of Ig molecules, no co-capping of Ig molecules with the Con A platelets was seen· the motion of bound Con A receptors and Ig molecules was now independent. This provides the strongest evidence that Con A receptor modulation of Ig on the surface of B lymphocytes involves microtubular structures and is not an artefact generated by crosslinking of Ig molecules to Con A receptors on the cell surface.

The evidence for the involvement of microfilaments in the movement of molecules in the cell membrane is even more indirect and depends on the use of the drug cytochalasin B This agent has had a rather poor press recently and it is not clear how it interferes with microfilament function. A further complication is that different preparations of this drug have different activities. What is fairly clear however is that cytochalasin B will interfere with cap formation and in the right condi-

tions will lead to an 80% inhibition of cap formation induced by anti-Ig. When used in conjunction with colchicine, cap formation is almost completely blocked. The addition of cytochalasin B to cells that have already capped leads to a dissolution of the capped molecules (de Petris, *Nature*, **250**, 54; 1974)

These findings suggest that microfilaments as well as microtubules have a role in the movement of molecules on the cell surface. What is required now is some more direct evidence of the linkage of molecules on the cell surface to microtubules and microfilaments in the cytoplasm.

Another overexploited fishery

from our
Marine Vertebrate Correspondent

OVEREXPLOITATION of fishery resources is no new phenomenon. Examples range in emotive potency from the state of whale stocks, through the decline in numbers of the Atlantic salmon, to the humble North Sea herring and the Californian sardine. Developments in fishery technology, aimed at improving the catch–effort ratio, have generally produced increasingly efficient means of exhausting the stock.

There is no worse offender in this respect than the Japanese high-seas fishery for tuna which during the last two decades exhausted the stocks in the southern Indian Ocean and the western Pacific, before transferring its operations to the Atlantic and the eastern Pacific Oceans. The consequences of this fishery on the billfishes (sailfish and marlins) of the eastern Pacific are discussed in a recent paper by Talbot and Wares (*Trans. Am. Fisheries Soc.*, **104** (1), 1–12; 1975).

By 1963 the Japanese fishery had expanded to 10° north latitude, offshore of Central America, and heavy catches of yellow-fin tuna (*Thunnus albacares*) and striped marlin (*Tetrapturus audax*) were made. In time it spread further north and the marlin became the major exploited species. The success of this fishery resulted in increased fishing effort and in 1964 the catch of this one species approached 300,000 fish. Thereafter the catch declined until 1967, reached a high point in 1968 of around 320,000 fish, but dropped dramatically the next year to just over 200,000. A comparable change has been observed in the catches of blue marlin (*Makaira nigricans*) which attained a maximum (nearly 80,000) in 1963 and thereafter declined severely, only increasing slightly (to 30,000) in 1969. The sailfish (*Istiophorus platypterus*) similarly shows an overall decline

from a peak of nearly 400,000 fish in 1965 to 100,000 in 1969.

Talbot and Wares examine the possibility that these changes in catch may reflect abundance variations caused by differing sea temperatures but, except for one area, they find little evidence to support this. They do, however, find clear evidence of overfishing. The first peaks of abundance for each of the billfish species can be related to increased fishing effort, and the decline in catch has persisted in some cases even though the number of hooks fished has increased. Expressed in terms of hook rate (the catch per hundred hooks), it seems that the striped marlin declined marginally from 0.7 to 0 3 between 1968 and 1969, the blue marlin catch fell from 0.35 to 0.05 between 1959 and 1969, while the sailfish catch fell from nearly 3 to 1.2 between 1965 and 1969. Clearly, in the cases of both the blue marlin and the sailfish the decline has been severe and indicates overfishing and depletion of the stocks. And the average weight of these fish has declined, which is also evidence of overfishing.

The reduction in numbers and weight of these billfishes may have considerable consequences for the sport fishery of the western Mexican and Californian coasts This sport fishery has provided an important contribution to the income of Pacific Mexico since the second world war. Talbot and Wares point out that the reduction in average size of the fish caught has already made it a less spectacular sport But they suggest that with the declining returns per unit effort the Japanese fishery may well decrease, leaving enough of the smaller billfishes to maintain the sport fishery

Exciting days over for reverse transcriptase?

from Karin Moelling

IT is five years now since Temin and Baltimore reported the existence in RNA tumour viruses of a reverse transcriptase which can make a DNA copy from the RNA genome. For some time progress on the characterisation of this new type of enzyme filled the front pages of the journals. But results on the characterisation of the enzyme are no longer so spectacular, and have become matters for hard working biochemists.

What do we know about the viral reverse transcriptase? Research was concentrated on the avian viral reverse transcriptase as large amounts of avian viruses can be isolated — and were generously supplied by J. Beard.

We learnt that the purified enzyme transcribes natural viral RNA very efficiently, for which it requires an RNA primer which was identified as a tryptophan tRNA (Dahlberg *et al*, *J. Virol.* **13**, 1126, 1974). In addition to the RNA-dependent DNA polymerase a DNA-dependent DNA polymerase is involved in the synthesis of the double-stranded DNA product Furthermore an RNase H activity seems to play a part. All these activities are coded for by the viral genome as was shown with avian viral temperature sensitive (ts) mutants (Verma, Mason, Drost and Baltimore, *Nature*, **251**, 27; 1974).

Enzyme from murine virus

One would have expected it to be simply a matter of routine to generalise the knowledge about avian viral reverse transcriptases to those of viruses from other species. This was, however, not the case. Mammalian viral reverse transcriptases could copy synthetic templates such as poly (rA). oligo (dT)—but did not seem to be able to carry out what they were given their name for doing, the reverse transcription of exogenous viral RNA into DNA! The RNase H seemed to be absent as well.

So the initially fast progress was followed by a series of negative results. But the results obtained with the avian enzyme were so well established that nobody could have seriously questioned their relevance also for mammalian viral enzymes. Therefore it did not come as a surprise when finally three detailed analyses showed that murine leukaemia viral reverse transcriptases had all the properties of avian enzymes: natural RNA transcription, presence of RNase H in a single polypeptide with the polymerase activities (in two of the three reports) and proof of its viral, not cellular, origin on the basis of its exonucleolytic mode of action (Moelling, *Virology*, **62**, 49; 1974; Gerard and Grandgenett, *J. Virol.*, **15**, 785; 1975; Verma, *J. Virol.*, **15**, 843; 1975).

What was the problem with the mammalian viruses? Apart from inadequate assay conditions used in some cases the starting material seemed to be important Mammalian viruses may be more sensitive to manipulation and the enzyme seems to be inactivated more readily.

As far as the RNase H is concerned, there was still a confusing matter left to be settled· Gallo's group reported that they could separate the RNase H from the viral reverse transcriptase (Wu, Sarngadharan, and Gallo, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 1871; 1974) which suggested that it could be a host cell contaminant.

This problem seems to have been nicely clarified by the latest paper of Gerard and Grandgenett (*J. Virol.*, **15**, 785; 1975). Like good diplomats they show that both results are correct: there is one RNase H which can be removed from the transcriptase; another (the viral one), which cannot, is present in smaller amounts and may have been missed by Gallo's group. The one which can be removed is very small and looks to me on first sight similar to the 'mini'-RNase H recently described as one of the cellular RNase H molecules in calf thymus cells (Buesen and Hausen, *Eur. J. Biochem.*, **52**, 179; 1975). It remains to be shown that the removable RNase H is really of cellular origin. The ultimate proof of the presence of viral RNase H in the single polypeptide murine viral reverse transcriptase molecule must come, as with the avian enzyme, from viral ts mutants.

The enzymatic properties of the reverse transcriptases of viruses from avian and at least one mammalian species, the murine one, seem quite similar. But in spite of their enzymatic relatedness they look structurally quite different: the avian reverse transcriptase has been described as a two polypeptide complex of molecular weights 110,000 and 70,000, called β and α respectively, and the murine viral reverse transcriptase consists of a single one. But there are also reports (Verma *et al.*, *J. Virol*, **13**, 1075; 1974; Gerard and Grandgenett, *J. Virol.*, **15**, 785; 1975) which offer two or even three subunits. The number of subunits may not be very relevant — except if some of them are host factors which supply functions missing in the single viral subunit. Indeed the purified viral enzymes are deficient in properties which they must exhibit *in vivo*: *in vitro* they are only capable of synthesising short DNA sequences which are not representative of the total genome.

I do not believe, however, that some of the described subunits are cellular factors. It seems much more likely that the smaller ones are degradation products of a larger one. So far, this has only been shown in the case of the avian viral reverse transcriptase whose larger polypeptide spontaneously undergoes transition to the smaller one, a process which can be stimulated by mild protease treatment (Moelling, *Cold Spring Harb. Symp. quant. Biol.* **39**, 969; 1974). Tryptic peptide pattern analysis by Gibson and Verma nicely confirms this relationship between β and α (*Proc. natn. Acad. Sci. U.S.A*, **12**, 4991; 1974). To finally prove that the larger molecule β is the actual reverse transcriptase it must be isolated and

characterised — a difficult task, as β is very labile. Proteolytic degradation products may still retain some enzymatic properties, especially response to synthetic templates — as is the case with the isolated avian breakdown product α.

If the β subunit is the real avian viral transcriptase, it might correspond with the single polypeptide murine viral enzyme. But this is so far unproven. Two properties of the murine enzyme bear a strong resemblance to those of the α subunit: its low affinity for templates and its rather low response to natural RNA templates, which can be dramatically stimulated by addition of primers. It may therefore very well be that the actual mammalian viral reverse transcriptase has not yet been identified.

Perhaps the question of what the viral reverse transcriptase looks like cannot be answered by isolating the enzyme from the virus. One may have to look instead at the intracellular state of the enzyme. This has been done by Gallo's group (Mondal, Gallagher and Gallo, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1194; 1975), who found interesting size differences between the reverse transcriptase from virus-producing cells and that of extracellular virus particles : the intracellular one is larger. It is not yet clear whether the high molecular weight class is an aggregate of the low molecular weight form and there is no evidence to correlate the two size classes with the avian β and α molecules.

One remaining problem is the small size of the DNA product of the reverse transcriptase. Baltimore and Duesberg recently made some progress here by increasing the deoxyribonucleotide concentration in the *in vitro* reaction, but the large amounts of radioactively labelled precursors required will be too expensive for normal use. Perhaps addition of cellular ligases will improve the size of the DNA product. Another important achievement would be the synthesis of a DNA product which represents all regions of the RNA template equally well—not just a small region in large amounts.

Furthermore the role of the RNase H needs to be shown. Does it remove the RNA in order to allow double-stranded DNA synthesis to occur? Such a mechanism was suggested soon after its discovery and is now also incorporated in the Cooper and Wyke replication model (*Cold Spring Harb Symp. quant. Biol.*, **39**, 997; 1974) But other models, requiring a complicated interaction between cellular and viral enzymes, have been proposed and recently supported (Leis *et al.*, *J. Virol.*, **15**, 484; 1975) Cooper and Wyke point to another interesting question: How

is the RNA primer removed from the RNA template to allow transcription of the anti-primer region?

None of these unsolved problems has affected the great usefulness of the viral reverse transcriptase in identifying the presence or involvement of RNA tumour viruses—particularly in human neoplasias. One still hopes for a specific inhibitor in order to test its effect on tumour growth—inhibition of reverse transcription is the only known virus-specific step which would not affect normal cellular functions Here H. Temin might object: he believes a reverse transcriptase plays a part not only in viral replication but also in normal cell development, for example in gene amplification. So far there is only weak evidence in favour of this exciting idea—but Temin was right once before[1]

Androgens converted to oestrogens

from our Steroid Biochemistry Correspondent

ALMOST 20 years ago it was demonstrated that androgenic steroids could be converted to oestrogenic ones even in the absence of steroid-producing endocrine organs: administration of testosterone to adrenalectomised ovariectomised women increased the urinary excretion of oestrogens. Recent studies have been concerned with the sites where such an aromatisation may occur and with the possibility that even a low level of conversion has an important effect at those sites.

Most tissues, including liver, seem able to bring about this conversion. Breast fat can form oestrogens (Nimrod and Ryan, *J. clin. Endocr.*, **10**, 367–372; 1975) and both abdominal and axillary fat can convert androstenedione to oestrone. This conversion by adipose tissue is surprising as one might expect the lipophilic steroid to be protected from the active enzymes by dissolving in the fat. Even though the rate at which oestrogens are produced *in vitro* by adipose tissue is very low, the large proportion of adipose tissue in the body (up to 30%) may make this tissue an important source. Oestrogens may have an important role in the aetiology and treatment of breast cancer; a large proportion of tumours are known to be oestrogen dependent and contain oestrogen receptors. But fat from normal breast tissue and that from subjects with cancer seems to have identical aromatising ability. Although oestrone is the main product formed, small amounts of oestradiol are also obtained.

Oestrogens may have a role in hair

growth and the presence of the aromatising enzyme system in anagen hair roots has also been demonstrated recently *in vitro* (Schweikert, Milewich and Wilson, *J clin. Endocr ,* **40**, 413–417; 1975).

Diencephalic tissue from human foetuses (Naftolin, Ryan and Petro, *J clin Endocr.*, **33**, 368–370; 1971) or limbic areas of rat brain (Lieberburg and McEwen, *Brain Res.,* **85**, 165–170, 1975) are able to aromatise testosterone or androstenedione but such conversion is negligible when cerebral cortical tissue is used. Whereas the radioactivity associated with oestradiol accounted for less than 1% of the radioactivity in the whole homogenate of the limbic areas of rat brain, in the nuclei oestradiol radioactivity counted for almost half the total. Although oestradiol could have been formed peripherally and taken up by the brain, the evidence would seem to show that oestrogens can be produced from C-19 steroids such as testosterone and androstenedione.

Marked changes in reproductive function can be caused by the administration of either testosterone or oestrogens to neonatal rats. This and other evidence suggests that the conversion of androgens to oestrogens in certain areas of the brain may have important effects on brain differentiation, sexual behaviour and the production of pituitary hormones.

Dilatancy and aftershocks

from Peter J. Smith

DILATANCY models are generally thought of in connection with either earthquake precursors or man-made earthquakes such as those induced by fluid injection at Denver, Colorado, during the mid-1960s. And though not everyone would agree on precisely how and why the migrating pore fluids account for the phenomena attributed to them, it is clear that if dilatancy is applicable at all it must be applicable to seismic activity extending over at least tens of years (because the precursors of very large earthquakes appear several decades ahead of the main shock) But what part, if any, does fluid flow play in aftershock sequences which also occur within this time scale? The question was first investigated by Nur and Booker (*Science,* **175**, 885; 1972) some years ago. But in having another look at it, Robinson *et al* (*Geophys. J ,* **41**, 37; 1975) have made an unexpected and encouraging discovery—encouraging because it shows that dilatancy concepts may be adapted successfully to explain phenomena at least one step removed

from those for which they were originally conceived

The particular sequence studied by Robinson and his colleagues was that of the Inangahua, New Zealand, earthquake of 1968 (magnitude 7 1). The general properties of aftershock sequences, however, are already well known. Thus the frequency of aftershocks immediately after a large shallow earthquake is typically thousands a day and decays with time to perhaps ten or fewer shocks a day 100 days later Up to a year at least, the frequency is approximately inversely proportional to time and is related to magnitude (of the aftershocks themselves) through the well known Gutenberg–Richter equation in which log (frequency) is proportional to magnitude with a constant of proportionality b (the so-called b value) Geographically, aftershocks are closely related to the fault region of the main shock, and most of them have focal mechanisms similar to that of the main shock.

When Adams and Lowry (*New Zealand R. Soc. Bull.,* **9**, 129, 1971) investigated the Inangahua aftershocks a few years ago, they found them to be no exception to these general rules The b value was roughly unity, the shock frequency varied as $(time)^{-1\ 05}$, the epicentres lay within an elliptical area about $45\ km \times 25\ km$ extending SSW from near the main shock's epicentre, and both the main shock and most of the aftershocks were apparently due to thrust faulting But Adams and Lowry only looked at the first 40 days of the sequence Robinson *et al.*, by contrast, returned to study the sequence 3.6 years after it had begun, by which time the magnitude level had decreased to that of microearthquakes. What they found was that the b value was still about 1 (having remained constant for more than 3½ years and over a magnitude range of 5), that the shock frequency had continued to decrease with time in the same way (actually as $(time)^{-1\ 06}$) and that the new epicentres were distributed as the old (the elliptical area had contracted marginally) But the faulting had changed completely, from the dominant thrust movement of the main shock and early aftershocks to the main normal movement of the later aftershocks

On the face of it, this is surprising The regional tectonic stress is compressive and thus hardly conducive to normal faulting unless both the stress is reduced to a low level and material is removed at depth. The earthquake and its aftershocks themselves will reduce the stress, but what could remove the material? The obvious explanation, of course, is that the pore fluids which entered the source region before the earthquake have now flowed out again. In general terms, the

normal faulting associated with the later aftershocks will therefore be due to the subsidence following the outflow. In short, the change to normal faulting late in the aftershock sequence is apparently a natural consequence of the pre-earthquake dilatancy.

Nuclear friction

from P. E. Hodgson

MANY complicated interactions take place when two nuclei collide at high energies, so that it is impracticable to develop a detailed quantum-mechanical theory. Instead, it has been found possible to understand some of the more important qualitative features of these interactions by making use of classical concepts such as orbit theory, friction and the behaviour of drops of liquid.

Among the more notable features of the energetic collisions of heavy ions is the rather distinct division between interactions in which a few nucleons are transferred from one ion to the other, with little loss of energy, and the so-called 'strongly damped' collisions in which the ions lose a substantial fraction of their energy. For each type of interaction, particular scattering angles are favoured, depending on the energy of the interaction.

In some cases the strongly damped inelastic collisions have energy losses as high as 200 MeV even though the final nuclei are very similar to the initial ones. This suggests 'that the nuclei can become highly excited in the interaction without substantially losing their identities or their original trajectories. After the interaction it is found that the ions have significantly less energy than they would have gained from Coulomb repulsion alone if they had started from a position of rest with their surfaces just touching.

In addition to these direct reactions, it is always possible for the two ions to coalesce or fuse together to form a compound nucleus, and the cross section for this is substantially less than the total cross section.

Beck and Gross (*Phys. Lett.*, **47B**, 143; 1973) have proposed that these phenomena may be understood if we think of the nuclei as experiencing strong frictional forces as they move in each other's field. These frictional forces convert kinetic energy into internal excitation energy, and thus reduce their relative angular momenta. In some cases the loss of angular momentum is so great that the nuclei cannot separate again, and they fuse together. In other cases they succeed in separating but only after strong mutual excitation has taken place.

This theory has recently been extended by Bondorf, Huizenga, Sobel and Sperber (*Phys. Rev.*, **C11**, 1265;

1975), who give a more detailed account of the processes that occur when one ion collides with another at high energy. The mutual interaction of the two ions may be described by a potential with three terms; first, the repulsive electrostatic or Coulomb potential, equal to $Z_1 Z_2 e^2 / r$ outside the ions and rather less inside, where Z_1 and Z_2 are the charges on the ions and r their distance apart. Second, there is the strongly attractive nuclear potential that essentially acts only within the volume occupied by the ions themselves and falls off exponentially outside. Third, there is the centrifugal potential $l(l+1)/r^2$ that accounts for the increasing difficulty for ions with high relative angular momenta l to approach each other; it is therefore repulsive.

At high energies l is large and the centrifugal potential dominates, so the total potential depends on l and r in the way shown for two values of l in the figure. The potential is more strongly repulsive for higher l and falls off rapidly as r increases.

This potential describes the forces acting on one ion due to the other, and classically speaking determines their orbits during the interaction. As soon as the ions touch each other additional energy-dissipating forces come into play, and these are usually represented by an absorbing potential. Quantum-mechanically this can be included by allowing the potential to become complex, as an imaginary potential has the effect of absorbing an incident wave, just as the refraction and absorption of a light wave can be described by attributing to the medium a complex refractive index.

We are now in a position to describe what happens to one ion that encounters another ion with orbital angular momentum l. If l is high the potential prevents the ions from touching, and the ion is elastically scattered or possibly the ions excite each other through their Coulomb fields. As l is progressively reduced the ions come closer together and begin to interact through their nuclear fields as well. Nuclear inelastic scattering can take place, and also the transfer of a few nucleons from one ion to the other. All these processes involve rather little energy, as the ions separate again with nearly the same energies as they had before the interaction These processes are represented by the dashed line on the figure.

At slightly lower values of l the ions interact very strongly; this happens quite suddenly because the nuclear densities rise very rapidly in the region of the nuclear surface. There is thus a critical l_{SDC} (strongly damped collision) below which the ions interact strongly. They stick together and nearly all their
Schematic representation of the energy for strongly damped collisions. For $l > l_{SDC}$, the ions fail to reach the separation R_i at which they interact strongly, and therefore elastic scattering or few-nucleon transfer occurs. For $l_{cr} < l < l_{SDC}$ they reach R_i and the radial and rotational kinetic energies are suddenly dissipated. The ions stick together for a short while, then a neck develops due to the repulsive Coulomb force, retarded by radial friction. The sketches in the lower part of the figure indicate the shape of the system as the strongly damped collision develops.

radial kinetic energy and angular momentum is suddenly dissipated. If R_i is the radial distance at which the nuclei initially touch, then such ions follow the path shown by the dotted line in the figure. After a sudden loss of energy that brings the angular momentum down to a value l the joint system continues to rotate like a dumbbell and further energy is lost in mutual excitation. These processes are extremely complicated at the nucleon level but may be described in a very general way using the classical concept of friction.

At this point we make use of a familiar observation from the behaviour of colliding drops of liquid, namely that what happens when they approach each other is not the same as what happens when they separate. As they come together, they remain spherical and join together only when their separation is the sum of their radii. But when they separate a neck forms between them and gradually narrows as they separate, finally breaking only when the drops are separated by a distance substantially greater than the sum of their radii when spherical.

We assume that the same thing happens for colliding nuclei. As they begin to separate, a neck forms between them and energy is continually

lost. They finally separate only when their distance apart is R_f, which is substantially greater than R_1.

For even smaller l values, so much energy is dissipated by frictional forces that the nuclei stick together permanently and a compound nucleus is formed. The highest l value for which this occurs is the critical l_c for fusion of the two nuclei.

The cross sections for these processes can be expressed in terms of the angular momenta using the expression for the angular momentum

$$l\hbar = mvR = k\hbar R$$

So that the cross-section

$$\sigma = \pi R^2 = \frac{\pi}{k^2} l^2 = \pi \lambda^2 l^2$$

Thus the total cross section for strongly damped collisions

$$\sigma_{SDC} = \pi \lambda^2 (l_{SDC}^2 - l_{cr}^2)$$

and the cross section for compound nucleus formation

$$\sigma_{CN} = \pi \lambda^2 l_{cr}^2$$

This simple picture of the interaction of heavy ions at high energies explains in a qualitative way some of the features that have already been mentioned.

First, it is clear that for $l > l_{SDC}$, the energy loss is quite small, while for $l < l_{SDC}$, it is very large. This explains the prominent gap in the energy spectrum of the outgoing particles. Second, the formation of a neck means that the ions are separated by more that the sum of their radii when they part, and so will have less repulsive Coulomb energy, again in accord with measurements. Finally, the cross section for the formation of a compound nucleus is much less than the geometrical cross section.

As an indication of the value of l involved in a typical reaction, Bondorf and colleagues consider the collision of 600 MeV ^{84}Kr with ^{209}Bi and find l_{SDC} =250 and $l_{cr} \approx 75$; showing how large a number of partial waves participate in these reactions. They developed a formalism connecting these parameters of the interaction with the classical angles of emission of the particles at the critical angular momenta, and included a coefficient of friction k by assuming that the frictional force is proportional to the velocity of the ion. From the angles of the observed peaks in the cross-section they deduced values of k and found that it varies with l. In this way they were able to account in a qualitative way for the characteristic angles of emission of the particles losing little energy and of those losing most of their energy.

These ideas have also been worked out by Gross and Kalinowski (*Phys. Lett.* **48B**, 302; 1974) using the Newtonian equations of motion with frictional forces. They calculated the interaction potential experienced by the lighter of the two colliding nuclei by averaging the nucleon–nucleus optical potential over the density distribution of the heavier, and assumed a predominantly radial form for the friction tensor. With this simple model they were able to account for a large number of experimental fusion cross sections, and their energy variation.

This model will have to be tested for many reactions over a range of energies but already the results are sufficiently encouraging to show the value of applying the classical concept of friction to nuclear reactions. As in the corresponding macroscopic situation, we use the idea of friction to take account in a simple way of very complicated processes we do not attempt to describe in detail, and to build them into a more comprehensive picture of the whole interaction.

Linking lymphomas with immunodeficiency

from R. T. D. Oliver

"NOWHERE in pathology has a chaos of names so clouded clear concept as in the subject of lymphoid tumours" (Willis, *Pathology of Tumours*, 49, 760; 1948). Twenty-seven years and three classifications later we understand little more about the basis for the wide range of pathological entities classified as lymphomas. The many immunological deficiency diseases are similarly confusing. At first glance the article recently published in the *Lancet* on Duncan's disease (Purtilo *et al.*, *Lancet*, i, 935; 1975) (X-linked progressive combined variable immunodeficiency, to give its full name) seems to add yet another syndrome to the growing list. But more detailed reading suggests that it may provide clues for a better understanding of both immune deficiency syndromes and lymphomas.

Purtilo and colleagues report on studies of a family where six out of eighteen male children in seven branches of the family died of a lymphoproliferative disease involving bone marrow, liver, spleen and CNS. In three of these children it was possible to document an infection with infectious mononucleosis virus (Epstein–Barr virus) at presentation or prior to the onset of the disease and two had histologically proven lymphoma of the gastrointestinal tract and CNS. The authors suggest that infection with the Epstein–

Barr virus in the face of relative inability to respond to that virus triggered the fatal proliferation of lymphocytes (presumably B cells in view of the well-known ability of the Epstein–Barr virus to cause transformation *in vitro* of human B lymphocytes, though the authors fail to describe detailed immunological studies of the patients or their normal relatives). They suggest that the immune deficiency is mediated by a sex-linked recessive gene because exactly 50% of males but no females in the involved arms of the family tree died with the disease. This observation is extremely interesting as to date five out of fourteen previously recognised sub-groups of immune deficiency disease have been shown to have a sex-linked recessive inheritance (Fudenberg *et al.*, *Paediatrics*, **47**, 927; 1971) and it is well recognised that the majority of lymphoma except nodular sclerosing Hodgkin's and nodular lymphomas have an excess of males. But the generally low incidence of familial lymphomas clearly indicates that, if X-linked genes are involved, other genes must be also, as is well illustrated in the family studies of children with acute lymphoblastic leukaemia by Till *et al.* (*Br. J. Haemat.*, **29**, 575; 1975).

There is evidence, from studies in experimental animals, that at least four different classes of immune response gene exist. The first to be discovered was that linked to the *H*-2 major histocompatibility region, which seems to be involved in initial antigen recognition by T cells (Katz and Benacerraf, *Transplantn Rev.*, **22**, 175; 1975), and in resistance to various leukaemia viruses (Lilly and Pincus, *Adv. Cancer Res.*, **17**, 231; 1973). The second class, found in some cases linked to genes controlling immunoglobulin allotypes, regulates quantitative aspects of antibody production (Braun, Eichmann and Krause, *J. exp. Med.*, **129**, 809; 1969). The third class are the sex chromosome X-linked genes which, to date, have only been shown to influence response to T cell independent antigens (Mozes and Fuchs, *Nature*, **249**, 167; 1974). The fourth class recently reported by Jormalainen, Mozes and Sela (*J. exp. Med.*, **141**, 1057; 1975) seems to mediate its effect by some form of suppression of preordained response. If there were this number of different immune response genes in man which could influence the response of patients with lymphoma (even if the disease was induced by a single aetiological agent), it would hardly be surprising that no two lymphoma patients had exactly identical pathology in their lymph nodes.

It is clearly going to be important to be able to detect the different classes of immune response genes in man. A start has been made by classifying lymphomas on the basis of differentiation

T or B cell markers on their surfaces (Brown *et al.*, *Lancet*, **ii**, 753; 1974), and there have been many studies of HL-A antigens in patients with lymphomas; but we are far from understanding the complexity of their interaction with other systems such as the sex-linked locus postulated by Purtilo *et al. In vitro* assays, such as that recently reported by Greenberg, Gray and Yunis (*J. exp. Med.*, **141**, 935; 1975) will undoubtedly play an important part in this work.

Quark soup, with glue

from W. T. Toner

IF nuclear matter is made of quarks, so are neutron stars. If the quarks move freely as long as they remain close to each other in the neutron, then they must move freely in the centre of neutron stars where the density is a hundred to a thousand times greater than that of the neutron itself. So argue Collins and Perry in a recent issue of *Physical Review Letters* (**34**, 1353, 1975).

The fractionally charged quark is still the simplest realisation of the abstract logic shown by group theoretical analyses of the spectroscopic patterns made by more than a hundred strongly interacting particles. Although all models have their problems, a remarkably successful fit can be obtained by considering quarks which are light and move freely in a potential well. This might be thought coincidental were it not for the evidence of experiments in which leptons (electrons, muons and neutrinos) scatter from the nuclear matter of neutrons and protons. In violent collisions, these electromagnetic and weak probes measure the degree of concentration of electromagnetic or weak charge in the strongly interacting target: Δp is large and since $\Delta p.\Delta x \sim \hbar$, Δx is small. If the target is allowed to break up, its mass during and after the collision need not be precisely defined and ΔE in $\Delta E.\Delta t \sim \hbar$ can be large, Δt small. Violent inelastic collisions can thus be said to measure the instantaneous degree of concentration of charge. As is by now well known, the data show the large and 'scaling' cross section characteristic of the scattering from quasi-free point charges or 'partons'. The numerical values are most simply understood by assuming that the partons are the same fractionally charged, freely moving quarks that account for the spectroscopy. They seem free so long as we look quickly.

But our best efforts to produce quarks have failed, so how can they be thought to be real? There is no refuge in the abstractions of the algebra of currents since any theory which describes the data turns out to have the character of a free field

theory, and free fields mean free particles, or quasi-particles at the least.

The theorist is required to invent a glue to bind the quarks with the property that if they try to move too far apart the restoring force becomes very large, possibly infinite. But the closer they get together, the weaker it becomes: the quarks are asymptotically free. Such theories are being developed and some even have the very desirable properties of gauge invariance and renormalisability. Particle physicists are so used to forces which increase at short distances that they find such a behaviour peculiar and the talk of 'quark confinement bags' hard to swallow, although analogies in other branches of physics are not hard to find. Consider the electrons in a metal, liberated from the strong binding forces of their own atom by the proximity of others and able to migrate under the influence of infinitesimal potential differences until they reach the surface, where they meet a potential wall several volts high. Closer to home, there is the independent particle model of the nucleus.

If the long-range force binding quarks in elementary particles is not just large, but infinite, so that quarks can never be observed directly, it will be extremely difficult to verify an asymptotically free theory. The predictions are likely to depend as much on the values of the parameters as on the essential correctness of the ideas. For example, the simple prescription for electron–positron annihilation that the cross section is given by the sums of the squares of the quark charges is only valid in the asymptotic region, and where might that begin? It would be invaluable to have independent confirmation of the asymptotically free quark picture from a qualitatively different situation.

Collins and Perry argue that in the enormously dense matter at the centre of

---

A hundred years ago

IN an article in the July number of *Symons's Monthly Meteorological Magazine*, on the French floods, is an interesting calculation which will give Londoners some idea of what a "flood" means. Supposing we had a flood in the Thames, it would cover on the south bank, the whole of Battersea Park, Lambeth, Southwark, Bermondsey, and Deptford; and on the north bank, Fulham, Chelsea, Brompton, Belgravia, Westminster, and St. James's Park; while, as for the new embankment, a steamer might ply over the top of it.

from *Nature*, **12**, 261; July 29, 1875.

---

neutron stars the strongly interacting neutrons must overlap to such an extent that the strong, long-range forces—whatever their precise nature—will be screened and the quarks will no longer be confined to one group. They will interact rather weakly with each other and should move freely as if in a superdense gas or 'soup'. Since many of the properties of gases depend on correctly counting the number of independent states, their results differ from those of theories in which the neutrons and other composite strongly interacting particles make up the soup. Because the short-range forces which remain are weak, they should be calculable by perturbation (power series) methods. Detailed examinations of cosmological and astrophysical questions will be made in future papers.

Rabies

from Arie J. Zuckerman

THE two unassociated recent deaths from rabies in London underline the fact that even with modern intensive medical treatment there is little chance of recovery. Rabies is not declining in prevalence; on the contrary it is spreading, especially among wild animals (*Nature*, **242**, 228; 1973). The current outbreak in Europe is advancing in France along a front nearly 800 km long at a rate of about 30 km a year (*Nature*, **251**, 663; 1974).

Rabies virus is classified as a member of the rhabdovirus group, which includes a diverse collection of bullet-shaped RNA viruses from mammals, reptiles, fish, insects and plants. The virus particles contain two distinct major antigens, a glycoprotein from the virus membrane and an internal nucleoprotein antigen. The glycoprotein antigen elicits the formation of virus-neutralising antibodies which afford protection in animals against subsequent challenge with rabies virus. The same antibodies are probably also protective in man (*WHO Techn. Rep. Ser., No. 523;* 1973). Complement-fixing and precipitating antibodies to the nucleoprotein are devoid of virus-neutralising activity. The role of cell-mediated immunity in protection is as yet undetermined, but it may be crucial in the exposed individual.

Rabies virus is transmitted by contact, commonly through a bite. Human infection is usually acquired by bite but infection by aerosol has resulted from natural and laboratory exposure (the latter during vaccine preparation), and there is also some evidence of oral infection and aerosol contact in animals. The incubation period is 3 to 8 weeks. The virus spreads from the site of introduction to the central nervous system along the peripheral nerves.

Following infection of the central nervous system the virus may multiply in the salivary glands, in the kidneys and elsewhere and in some species in the muscle and the lungs.

Rabies is enzootic in all countries, except Australia and Antarctica, existing in two forms: urban rabies, propagated principally in dogs, and rabies in wildlife. Wild carnivores appear to be the main transmitters of epidemic and endemic wildlife rabies and methods of control have been reviewed in detail elsewhere (WHO Report, *loc. cit.*). Some progress has recently been made in the treatment and prevention of rabies in man. Ideally, before instituting treatment it is important to determine whether the biting animal was vaccinated and whether the animal was rabid. Local treatment of the wound is extremely valuable, especially when applied very early after exposure. This is followed by the combined administration of anti-rabies serum, preferably of human origin, and active immunisation. In many countries an immunisation schedule of 14 to 21 daily injections is being used and booster doses are essential when combined antiserum–vaccine treatment is employed A rabid patient should be isolated and treated in an intensive medical care unit.

The vaccines which have been used are of two types: those derived from the brain of adult or newborn animals and those derived from avian non-nervous tissue. Vaccine prepared from a Pasteur or similar strain of fixed virus grown in duck embyros has been developed in an attempt to eliminate the hazards associated with the brain tissue vaccine, which include neuroparalysis. Some progress has also been made in the purification of nervous tissue vaccines by extraction with fluorocarbon and other treatment. But even more promising are the vaccines produced in cell cultures. In the USSR and Czechoslovakia the Vrukovo-32 strain has been grown in primary hamster kidney cells, in France vaccine has been prepared in primary foetal bovine kidney cultures and in the USA and France an inactivated vaccine is being produced in human diploid cells with a Pasteur-derived PM strain adapted to cell culture. Three injections of this vaccine, given at intervals of 3 to 4 days in previously non-immunised subjects, elicit a neutralising antibody response which is much greater than that induced by 12 to 14 daily injections of either brain tissue or duck embryo vaccine (WHO Report, *loc cit.*). Indeed evidence of studies to date indicates that cell culture vaccines offer distinct advantages over existing vaccines of nervous tissue or avian origin, from the points of view of both safety and potency. Clearly careful assessment and evaluation of the newly developed cell

culture vaccines for man must continue. Pre-exposure immunisation of persons who run a high risk of repeated exposure, such as veterinarians and field naturalists, is highly desirable. Such immunisation consists of three injections of a potent vaccine at 5- to 7-day intervals followed by a booster injection a month later and subsequently at intervals of 1 to 3 years. Prophylactic vaccination of dogs and cats and other species where appropriate is most important, as are local administrative programmes and international control of transfer of animals. But the control of rabies in wildlife continues to challenge man's ingenuity.

Nuclear reactor in the jungle

from S. A. Durrani

An international symposium on the Oklo phenomenon was held at Libreville in Gabon on June 23–27, 1975, under the joint auspices of the International Atomic Energy Agency (IAEA) and the French Atomic Energy Commission (CEA), and sponsored by the Government of Gabon.

NATURE, it would seem, had anticipated man by something like 1,800 million years in bringing about the first self-sustained nuclear chain reaction on the Earth. And, contrary to common belief, it was not in the squash court of the University of Chicago in December 1942, but in the wilds of what is today the Republic of Gabon at a place called Oklo that this fantastic phenomenon took place.

The history of the discovery of the phenomenon, as it unfolded during the symposium, is briefly as follows. In June 1972, a team working under the direction of Dr H. V. Bouzigues at the CEA service laboratory at Pierrelatte in France noticed a marked anomaly in the abundance of the uranium-235 isotope (0 7171±0.0010 in atomic per cent instead of the normal 0.7202± 0.0006) during the certification of a secondary standard of UF_6 by the gas diffusion method. Later, much larger depletions of this isotope were discovered (down to 0.621%, and eventually to 0.296% [235]U) in uranium samples from this source, which was traced back to the Oklo deposit. First positive proof of the hypothesis that a natural chain reaction was responsible for the depletion of the fissile component was furnished by Mme M. Neuilly and co-workers of CEA through the measurement of the ratios of fission-product rare earths detected in the ore by the spark source mass spectrometry technique. Two simul-

taneous submissions by the above two groups on September 25, 1972, to the Proceedings of the Academy of Sciences, Paris, announced the discovery and the proposed explanation of this remarkable phenomenon It was pointed out that at the time of the reaction the natural abundance of the relatively fast-decaying [235]U isotope was more than 3%. This natural 'enrichment', helped by the moderation of the fission neutrons by the water content of the soil which enhanced their fission efficiency, and possibly by the relative absence of neutron-absorbing elements in the surroundings, allowed a nuclear chain reaction to develop. It is perhaps worth mentioning that such a natural chain reaction had already been predicted, on theoretical grounds, by several scientists, notably by P. K. Kuroda as early as 1956. The scientific secretary of the symposium, Dr R. Naudet of CEN, Saclay, has since late in 1972 been leading the 'Franceville Project' established by the French CEA to investigate the phenomenon, and has done a great deal to promote its study internationally.

One of the questions discussed at the conference (for example by E. Roth of CEN, Saclay) was whether the Oklo phenomenon was unique. The general feeling was that such propitious circumstances must have occurred elsewhere on the Earth. The timing (~1,800 Myr ago) may well have been optimal. The role of organic matter in producing 'super-concentrations' of uranium in the Franceville basin was delineated by J. Connan (SNPA-Pau, France). At earlier times, organic matter may not have been present in sufficient quantities, whereas more recently the [235]U component would have diminished. One intriguing possibility being discussed in the corridors of the conference was whether the radiation accompanying Oklo-type reactions over the globe could have played a role in the furthering of the evolutionary process. (It is believed by some palaeontologists that the origin of mitotic, nucleated cells lies somewhere between 1,500 and 2,000 Myr ago.)

The fact that most of the fission products seem to have stayed put over ~1,800 Myr has great relevance to present-day waste disposal problems in the field of nuclear reactors (and nuclear explosions). These implications were reviewed by R. D. Walton (Division of Waste Management and Transportation of USERDA) and by C. Fréjaques (CEA). The latter pointed out that [239]Pu seems to have hardly moved at all during its half-life of ~24,000 yr. Such conclusions, if confirmed, would be of profound importance in the future development of nuclear energy, both peaceful and destructive.

review articles

Archaeological evidence of environmental change

G. W. Dimbleby*

Pollen analysis, particularly combined with data from other animal, vegetable and mineral remains on archaeological sites, can yield much information on climatic conditions and the development of agriculture in prehistory. There remain, however, considerable problems of interpretation where the indications from different sources are at variance.

IT is now commonplace to read accounts of changing environmental conditions over periods of thousands of years, sometimes even going back into the earlier stages of the Pleistocene. This is largely due to the great development of pollen analysis, combined in later periods with radiocarbon dating, which has now been applied in many different parts of the world and to many different types of deposit. Evidence of climatic change is also indicated by other features such as change in sea levels or invertebrate faunas. In the more remote past these changes could only have been due to changes in climate and other secular factors determining the environment.

In later times, however, and especially in the past 10,000 years, man was operating within the landscape, using powerful ecological tools such as fire or agricultural practices. Some effect of these activities is often detectable in the pollen record of lake deposits or peat bogs; for instance, a reduction of tree pollen relative to herb pollen[1], or the appearance of weeds of arable land[2]. There are circumstances in which it is not easy to distinguish secular changes in the environment from the anthropogenic effects. For example, in the past 2,000–3,000 years of the postglacial period in Britain there has been a proportionate increase in the representation of birch (*Betula*) in the tree pollen totals[3]. This could be due to a progressive cooling of the climate, to a progressive acidification of soils, or it could be due to the influence of man in creating a more open landscape, and in particular with his use of fire to do so. What can rarely be told from pollen analyses is where changes were taking place and with what intensity.

It is here that ecological investigation of archaeological sites themselves can often fill in the picture. Once man started constructing earthworks, that is, from the Neolithic onwards, in doing so he was burying a sample of the contemporary land surface and so preserving it for posterity[4]. Even before then, in the Mesolithic, he sometimes created conditions which produced the same effect: wind blown sand resulting from forest destruction on occasion buried a contemporary land surface[5]. These buried surfaces, and to a lesser degree the material of the earthworks themselves, can be studied by some of the conventional methods, appropriately adapted, and also by other methods which are not applicable to the aquatic situations which are the usual source of evidence of past conditions.

Before I go on to consider these applied techniques in more detail, one important point must be made. In a peat bog,

preservation of pollen and other organic remains can be very good; moreover, such remains are well stratified, though perhaps not always as perfectly as is sometimes assumed. A buried land surface, however, can preserve material in no better condition that it was at the time of burial; and if stratification in the contemporary land surface was disrupted, as for instance by the activity of soil fauna, it will be preserved in the same disrupted state.

Pollen analysis

The value of pollen analyses of buried soils must depend on whether pollen analysis can be usefully applied to terrestrial soils. There is now quite an extensive literature on this subject[6-10], and it seems quite clear that acid soils can not only provide a surface humus layer which contains a contemporary pollen spectrum, but that the mineral soil beneath contains a record in broad terms of the vegetation history of the site, brought about by the progressive downwash of the older pollen into the deeper layers of the soil. This record may cover hundreds or even thousands of years.

Base-rich soils may contain no pollen, or at best small quantities. Such soils are often actively worked by earthworms and other soil animals, so that stratification is destroyed. It can be argued, however, that microbiological breakdown of pollen is rapid, so that all the pollen in the solum is more or less coeval. If so, the pollen of all the samples counted can be totalled to give a single pollen spectrum[11].

Using pollen analysis of buried soils it has been possible not only to show the progressive clearance of areas such as the North York Moors, but within any one area to show what types of land use were in operation in the various periods[12]. Even on calcareous soils clear evidence of open country in the early Neolithic has been obtained by this method[11], and it seems that it remained open from then onwards.

The pollen analyses of buried soils can sometimes be tied in with profiles from adjacent peat or lake deposits, but in other cases there is no apparent correlation. For example Thorley's pollen profile from Lewes[13] indicates that forest cover of the chalk extended until the Middle Bronze Age, yet the analyses of buried soils of Neolithic age may show open conditions[11]. Such discrepancies may arise from the fact that a pollen spectrum from a peat deposit is of a regional character whereas one from a buried soil is essentially local and not necessarily representative of the wider area.

Finally under this heading one should mention that pollen analyses of archaeological sites may contain artificial concen-

*Institute of Archaeology, University of London, 31-34 Gordon Square, London WC1, UK.

trations of pollen, such as the remarkable high percentages of ivy (*Hedera*) pollen found in some Mesolithic and later sites[14]. Such concentrations are unparalleled in aquatic deposits.

Other botanical material

Archaeological sites may contain other plant remains, some of which are valuable indicators of environmental conditions. Frequently these are charred, though in special circumstances, such as waterlogged deposits (wells and so on) or the peculiarly anaerobic conditions of Silbury Hill, good preservation of uncharred material may occur. For instance, under Silbury Hill[15], and in the waterlogged Wilsford Shaft, moss plants were found which were still green. They were readily identified and indicated the existence of chalk grassland turf in Neolithic and Bronze Age times.

In the early 1950s Helbaek[16] carried out his extensive investigation of seed impressions on prehistoric pottery, but since then the development of the flotation technique[17] has increased enormously the direct evidence not only of the crop plants but also of the associated weeds (see, for example, Dennell[18]). In the New World much evidence about early food plants and their associated weeds has come from cave deposits, including human and animal coprolites[19]. Such evidence has been of outstanding importance in the quest for the origins of maize[20].

Charcoal and sometimes uncharred wood may be found on many archaeological sites. They are of limited value as environmental indicators because wood was a material collected by man for fuel and for constructional purposes. Such finds are therefore usually only of general significance. Nevertheless interesting facts may arise; for example, in spite of the poor showing of *Pinus* pollen in Zone VIIb deposits of Southern England, the charcoal of *P. sylvestris* is recorded in a number of sites through the Neolithic and Bronze Age[21,22].

Other plant remains may be found using the appropriate techniques. Bud scales have been isolated and identified from waterlogged deposits[23] and grass phytoliths may occasionally be found in large concentrations[24]. The ecological value of such records remains to be seen.

Animal remains

Vertebrate bones are often an abundant feature of prehistoric sites with a high *p*H. The larger bones are valuable evidence of man's use of animals and of their structural features, but they are of limited value as ecological indicators—except in so far as domestic animals represent a powerful ecological influence.

The smaller vertebrates—rodents, amphibia, birds—have received relatively little study. These groups present some difficulties of identification, but their potential as environmental indicators is considerable. One source of their remains, found occasionally on archaeological sites[25], is the regurgitated pellets of birds of prey.

Invertebrate remains offer the greatest promise as environmental indicators, but they can also offer formidable problems of identification. Important results have been achieved with molluscs[26]. In calcareous soils they can provide evidence of changes of environment; for example, the sequence from forest through clearance to grassland has been demonstrated a number of times by Evans[4]. As with soil pollen, their distribution in the soil profile can also give a broad picture of preceding environmental change, though it is not entirely clear how a degree of stratification comes about in a calcareous soil. More work still needs to be done on the ecological requirements of the critical taxa, but it is obvious that they provide a tool of great value.

To an even greater extent is it true that more ecological knowledge is required about the insects. The Coleoptera in particular may be found in considerable numbers and variety of species[27,28] and although groups such as dung beetles may be over-represented, many other species must derive from the

locality and therefore be of particular ecological significance. Insect remains are also proving to be an important feature of urban sites where they can indicate the nature and use of the premises in which they occur[29].

It has been found that the exoskeletal remains of mites may be preserved in waterlogged archaeological deposits[30] and these, too, may be of considerable environmental significance. Our knowledge of the ecology of many species is still inadequate, but there have been considerable advances in this direction in recent years (see for example ref. 31).

Soils and sediments

This is a source of information which is rarely, and then only indirectly, available to those working on aquatic deposits. A buried land surface may provide evidence both of the ecological community and of the soil with which it was associated. By comparing the soil profiles buried beneath earthworks of different ages in the same area, it is possible to show the sequences of soil development, which culminates in the present-day soils[12]. It can be demonstrated that on acidic parent materials the clearance of primary forest, followed by pastoral or arable agriculture, may institute a new process of soil genesis, resulting in a different soil—a more acidic and less biologically active one—compared with the mature soil which preceded forest clearance. By combining pollen analysis with observations on the particle-size distribution in a profile it is sometimes possible to show at what stage in the process the earthworms of the original mull humus were eliminated by the soil acidification. In one site at Goodland in Northern Ireland[32], there is evidence that Neolithic clearance and farming led to soil acidification, loss of structure and eventually peat formation, a conclusion which accords with Moore's recent conclusions from the pollen analysis of blanket peats[33,34].

Even on calcareous soils there is some suggestion of soil change. Some of the Neolithic soil profiles are very shallow, as though truncated. Evans and Valentine[35] have evidence of hill-wash associated with initial clearance of scarp slopes. Certainly chalk soils eroded massively in late prehistoric times, as evidenced by the dry valley fill[36] and by lynchet formation[37].

Multi-disciplinary approach

Though few sites contain material in all the categories described above, most sites contain several different types of evidence. It is important that wherever possible more than one approach should be used. In some instances the different lines of enquiry corroborate each other completely. At Silbury Hill, for instance, the analyses of pollen, molluscs, insects, seeds, mosses and the soil profile all fitted in with a picture of pastoral agriculture in an open landscape. There are circumstances, however, where the different approaches seem to give contradictory results; one may suggest wooded conditions and the other grassland. In some cases these are readily explicable, as at Windmill Hill, where the Neolithic buried soil seems to have been truncated, so that the pollen and mollusc analyses apply to different phases[26]. In other cases no such explanation is obvious[11], and we have to consider more carefully the nature of the evidence. Pollen grains and snail shells are very different in nature; they get into the soil in different ways and their persistence in the soil depends on different processes. Enough work has been done on both materials to show that consistent results are obtainable with each, but discrepancies show that there are factors we have not yet taken sufficiently into account in building an archaeological interpretation from the analytical data.

Just as conventional pollen analysis was widely used before questions were asked about the relationship of pollen spectra to vegetation in modern environments, so the interpretation of archaeological environmental data is now at the stage of having to pause and consider the validity of the obvious conclusion

indicated by the evidence. We cannot turn to modern equivalents of early farming environments in regions like Europe—they no longer exist. Perhaps this is another area in which experimental archaeology may help us to solve our present problem.

Origin of blanket mires

Peter D. Moore*

There are three possible causes for the formation of the peat deposits which blanket parts of the British Isles and Scandinavia. Climate and soil maturation each plays a part, but the contribution of human activity now seems to be larger than had hitherto been supposed.

THE upland, oceanic regions of the western British Isles and Scandinavia have extensive areas covered by deposits of peat, which have developed over a wide range of substrate and topography. The peat blanket is most extensive over plateaux and gently shelving depressions but shallower on or absent from steeper slopes[1]. In depressions, the stratigraphic profile may reveal the presence of former lakes, dating from late-Devensian times[2], or the remains of damp woodland and carr[3,4] below the blanket peat cover. The age and origin of the blanket peats has been the source of much controversy, but evidence now accumulating links their origin with prehistoric human activity. Until recently, the possible influences of this factor had been underestimated in favour of those of climatic change and developmental processes within soil profiles.

The age of blanket peats

Early work on blanket peat stratigraphy was carried out by Conway in the southern Pennines[4,5], where extensive deposits exist. Her conclusion, based on pollen analysis, was that the peats began forming during Atlantic times (about 7,500–5,000 yr b.p.), which seemed reasonable in view of the generally wet conditions which then prevailed. Many of the shelving depressions examined by Conway, however, contained peat-forming woodland communities before the spread of true blanket peat. More recent work by Tallis[7] on the peats of slopes and plateaux suggest a later date, at about the time of the elm decline pollen horizon, although some of his higher altitude diagrams (for example, Featherbed Moss[8]) have basal deposits predating the elm decline.

Pollen analysis of blanket peats from other areas,

summarised in Table 1, show that peat initiation often occurred at about the time of the elm decline, the exceptions being mainly the deeper peats of the southern Pennines. Smith and Pilcher[9] have recently collated radiocarbon dates of the elm decline and other widely used Flandrian pollen zone horizons to examine the basic assumptions of geographical synchroneity of vegetational change, which underlies the general application of the Godwin[10,11] zonation system. They found that the dates of most pollen zone boundaries differ considerably according to the geographic position of the site, whereas the elm decline horizon remains remarkably synchronous at about 5,300–5,100 yr b p. Whatever the cause of the elm decline, whether climatic change, prehistoric human activity[12] or disease[13], it seems to be a reliable guide to the date of origin of many blanket peats, at about or just before 5,000 yr b.p. Caution is required, however, in interpreting shallow blanket peat profiles, the base of which may coincide with a secondary elm decline[14]. Profiles from the Highlands of Scotland are difficult to interpret because of the indistinct nature of the elm decline in these areas[15].

Bartley[16] has published a radiocarbon date of $5,490 \pm 140$ yr b.p. from the base of a blanket peat profile on Rishworth Moor, West Yorkshire, which coincides with the elm decline This is slightly older than is normal for this horizon, but peat accumulation is likely to have been slow at the time and the resolution of ^{14}C dating therefore poor.

The elm decline is itself usually accompanied by palynological indications of human activity and forest clearance, but even in the shallow peat sites, which were initiated later than the primary elm decline, the basal deposits often give indications of considerable human activity[14,17]. It is this coincidence of peat initiation with evidence for human interference with vegetation which makes imperative a reappraisal of the generally assumed climatic origin of blanket mires.

Conditions and causes of peat formation

Peat accumulates when the total respiratory activity of producers, consumers and decomposers fails to attain the same level as primary productivity. In fact it is the depression of decomposition rates which is most critical and this is related to waterlogging. Any environmental change which leads to increased waterlogging will therefore favour peat initiation. The three main variables which could be invoked to account for blanket peat formation are climate, soil maturation and human clearance of vegetation.

Frenzel[24] has argued the case for a short period of cold climate in many parts of the Northern Hemisphere between 5,400 and 5,000 years ago. This is disputed by Smith[25] who considers that much of Frenzel's data could equally be attributed to human activity, especially in upland areas. Lamb et al.[26] suggest that both rainfall and excess drainage water in Britain actually decreased by about 10% between 4000 and 2000 BC. Sources of evidence for climatic changes during this time are few, and often themselves of a botanical nature, for example, peat growth rates[27], and such evidence is open to alternative interpretations Iversen's[28] use of ivy, mistletoe and holly as climatic indicators on the Continent and its subsequent criticism by Troels Smith[29] on the grounds of prehistoric man's interest in these plants is a well known example of the misinterpretation of botanical evidence which is possible during this complex and confused period. It is generally agreed that Flandrian tree lines reached their maximum altitude at this time[30,31], but their subsequent retreat cannot necessarily be regarded as an entirely climatic effect. Independent evidence for climatic change at the time of the onset of blanket peat formation is, therefore, not adequate to allow quantification.

Blanket peat could be regarded as the terminal stage in soil maturation for high rainfall areas, in which case its formation is essentially pedogenic. Godwin (in ref. 30) took his position, considering podsolisation in high precipitation/evaporation conditions a prerequisite for peat formation.

Dimbleby[32], however, considers this unlikely because sub-peat soil profiles are frequently immature and do not display fully developed podsolic characteristics. Since many blanket peats are developed over soils which, though presumably waterlogged, do not give the impression of having suffered intense leaching[33], it is unlikely that podsolisation, pan formation and resultant drainage impedance is the main causative factor in peat initiation. In some Irish sites[34,35], Mitchell has stressed the role of pan formation as a cause of waterlogging, consequent on prehistoric ploughing. Often the depth of the thin pan corresponds with the depth to which the plough penetrated. Human land use may, therefore, be intricately connected with soil processes before peat initiation at some sites, but this explanation cannot be accepted for the majority of upland peats in Britain, where neither ploughing nor podsolisation necessarily precede peat initiation. Nor is it likely that such soil processes, even in worsening climatic conditions, could be responsible for peat initiation in the absence of human forest clearance.

For many years circumstantial evidence has been accumulating which links prehistoric human activity with the initiation of blanket peat deposits[18,35]. Dimbleby[37] showed that forest could be converted into moorland as a result of Bronze Age forest clearance and Simmons[18] suggested that even Mesolithic communities could have initiated such changes in Dartmoor. Simmons[38,39] has attempted to construct an explanatory model which might account for these vegetational changes, concentrating particularly on the capacity and the motives of Mesolithic populations for producing them. He concludes that their ecological impact in upland Britain would have been small, but that their relationship with red deer as an important food resource would have provided them with ample motive for upland clearance. Neolithic peoples, complete with truly domesticated herbivores, must have had even stronger motives for upland forest clearance and the general use of such areas for grazing.

Table 2 Summary of data concerning increased stream discharge following the deforestation of a watershed

Site	Forest type	Increased discharge on felling (%)	Author
South Appalachians, USA	Oak/hickory	15	Swank and Douglas[41]
Colorado, USA	Aspen, mixed conifer	22	Bates and Henry[42]
Colorado, USA	Lodgepole pine	25 (after 40% clearance)	Hoover and Leaf[43]
Japan	Mixed deciduous/conifers	8–24	Nakano[44]
New Hampshire, USA	Maple/beech/birch	40	Bormann and Likens[45]

The vital question which must be asked, however, is what would be the hydrological consequences of forest modification, since peat initiation is most closely linked with soil hydrology. The question is particularly relevant to blanket peat formation since the topographical features of the sites involved are often water-shedding rather than receiving. Removal of a tree canopy from such a situation would increase the supply of ground water by reducing the transpiration demand of the vegetation and also by reducing the water interception of the canopy, much of which would evaporate once more without reaching the ground. The considerable body of experimental data now available permits the estimation of water gains resulting from forest clearance. Table 2 is a summary of data derived from experimental deforestation of watersheds bearing a variety of forest types.

There are many problems associated with the interpretation of such figures and extrapolation from them to other situations[46]. In particular one should be mistrustful of data from watersheds where there has been inadequate calibration before felling; one must also consider the forest types involved, since coniferous trees intercept more water than deciduous ones[40]; and one must take into account the climatic conditions in which the data were obtained, particularly those factors influencing evaporation. The figures obtained by Swank and Douglas are perhaps the most acceptable in terms of rigorous calibration, but in the context of a more oceanic Britain during Neolithic times, with lower evaporation rates, a figure of 10% increased discharge following clearance would be a more reasonable estimate. Studies of soil water under different vegetation types[47] and direct studies of interception losses in forest stands[48] in Hampshire, England, confirm that 10–20% more water would be available on removal of a forest canopy.

Clearcutting of forest in Finland has been reported as causing a rise in water table of 38 cm (ref. 49), and thinning of a beech forest in Denmark has resulted in the death of remaining trees by waterlogging as a consequence of the higher water table produced[50]. It is this kind of effect which leads to the use of fire as a means of watershed management in the USA[51,52]. There are even some situations in which the clearance of a catchment can be directly correlated with peat development in the areas receiving runoff. For example, Skarzynska[53] has described such a situation in Poland where settlements of the Luzyce culture (Iron Age) in low lying areas were literally swamped by peat-forming plant communities as a consequence of the deforestation of the surrounding catchment. In more recent times, alder/spruce woodlands in Czechoslovakia have been converted to waterlogged meadows following clearance[54].

Having established that human clearance of woodland (by felling or fire) or even woodland thinning (by selective felling or free grazing by sheep or goats[55]) could modify hydrological regions very substantially, one must consider which prehistoric cultures may have been responsible for peat initiation in different parts of Britain. In some areas the influence of Mesolithic man in the uplands was considerable and Simmons[18] has implicated these cultures in his explanation of habitat changes on Dartmoor. Pennington[56] has described evidence for increased runoff in parts of the Lake District in late Mesolithic times and also for the development of blanket peat over mor humus and mineral soils during Neolithic times. Many radiocarbon dates for the early Neolithic are older than 5,000 yr b.p. (ref. 57) and give weight to the argument that many of the deeper, high-level blanket peats of western and northern Britain could have been initiated as a result of the activities of these peoples. Such activity may have involved no more than the free grazing of their stock coupled with occasional firing. In Ireland, the

extensive work carried out by Goddard[58] and Smith[59] suggests that, although some high altitude blanket peats began their formation during Neolithic times, the majority of peats studied were initiated in Beaker and Bronze Age times. Shallower and lower altitude peats on Exmoor[14] began to form during the Iron Age and during later times depending on local conditions of topography, climate and human land use, with the last-mentioned often acting in a critical manner to effect the crossing of the hydrological threshold for peat formation.

Three main conclusions emerge from these data. In the first place, prehistoric man was theoretically capable of influencing catchment hydrology in ways which would create effects of magnitude similar to those derived from major climatic changes. Second, circumstantial evidence from the dates of blanket peat initiation and from pollen assemblages at the base of these deposits, indicates man's involvement. Regional, topographical and altitudinal metachroneity is to be expected. This reflects the differing intensities of man's activities experienced in various areas and also the intensity of activity required for peat initiation at different sites. Finally, the soil changes associated with peat initiation are most satisfactorily explained as a consequence rather than a cause of the demise of forest and the development of peat.

Chandler Wobble, earthquakes, rotation, and geomagnetic changes

Frank Press & Peter Briggs

Department of Earth and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

A pattern recognition algorithm can be applied to the seismicity of major earthquake belts, to the amplitudes of Chandler Wobble, to changes in the rotational velocity of the Earth, and to the drift of the eccentric geomagnetic dipole for the years 1901–64. The patterns which emerged suggest that all of these diverse phenomena are related.

THE causes of the Chandler Wobble and of variations in the length of the day remain a subject of speculation. The suggestion that movements accompanying great earthquakes excite the wobble faces the difficulty that the displacements may not be large enough[1,2]. But large, slow deformations (over hours or days) can occur in the epicentral area before and after a major failure and when these movements are added to the seismic slip that occurs with the main shock, the combined displacements seem to be large enough to excite the Chandler Wobble[3]. Short term changes in the length of the day (over periods of about 2 yr) have been related to variations in zonal wind velocity[4] and long term changes (over periods of about 10 yr) have been attributed to motions in the fluid core[5,6]. Presumably, the motion of the eccentric dipole is related to fluid motion in the core, and the compensatory changes required to conserve angular momentum of the Earth show up as changes in the length of the day.

Anderson has suggested that volcanism and climatic changes may be related to all of these phenomena[7]. According to his hypothesis, major volcanic eruptions lead to zonal wind changes which affect the rotation of the Earth, both on a short and long term basis. Small perturbations in the velocity of rotation trigger the release of the large amount of elastic energy stored in the lithosphere because of rotational processes, setting off global seismic activity and exciting the Chandler Wobble. The main supporting argument is the apparent correlation between global seismicity, fluctuations in rotation and amplitudes of the Chandler Wobble, and the indication that short term zonal wind changes seem to affect the rotation rate.

Here we apply a method of pattern recognition (ref. 8 and I. M. Gelfand *et al.*, unpublished) to see if we can detect a pattern in these diverse phenomena.

Pattern recognition algorithm

In a learning phase the computer is told into which of two groups—G_1 (26 yr) and G_2 (38 yr), associated with the amplitude of the Chandler Wobble and its decay, respectively—the build-up of data are to be placed for each of the 64 years from 1901 to 1964. Chandler Wobble data smoothed by taking 6-yr running averages are used[9].

For each year a series of heuristic questions is posed (Table 1) and answered yes/no, or 1/0 in binary code. The specific parameters for each question are assigned following a preliminary survey to obtain the best separation between G_1 and G_2. For example, for Question 16 (Table 1), many time windows were tested but the values used (present year) gave the best discrimination in that 73% of G_1 and only 10% of G_2 received a yes answer.

Characteristic traits for G_1 and G_2 years

The answer matrix consisting of the binary answers to the questions for each year (as well as a third category for unanswerable questions) is then examined to see if certain patterns emerge which characterise G_1 or G_2 years. A trait is a combination of answers to questions taken three at a time, two at a time or one at a time (triplet, doublet or singlet traits, respectively). For the 22 questions in Table 1 there are 13,288 possible traits. If a trait appears more than K_1 times in G_1 and less than $\tilde{K}_1$ times in G_2 it is identified as a characteristic trait for G_1 years. Similarly constants K_2 and $\tilde{K}_2$ are used to identify characteristic traits for G_2 years. For the questions cited in Table 1 the values $K_1 = 14$; $\tilde{K}_1 = 2$; $K_2 = 27$; and $\tilde{K}_2 = 2$ were used to obtain a few, in this case eight, independent characteristic traits for both G_1 and G_2. In a sense, we have used pattern recognition as an hypothesis selector and have checked thousands of possible hypotheses against data.

In a final step or predictive phase, a vote is taken for each year, with each G_1 characteristic trait assigned a positive vote and each G_2 characteristic trait a negative vote. For each year, the algebraic sum of G_1 and G_2 characteristic traits (the 'netvote') is used in most applications to predict future events[8], for example, to predict future build-ups or decays in the amplitude of the Chandler Wobble. These procedures may seem arbitrary, but pattern recognition lacks a formalism, as yet, and specific methods are justified by control experiments and other tests (I. M. Gelfand *et al.*, unpublished). The agreement between the netvote of characteristic traits and the Chandler Wobble amplitude data for the years 1901–64 is excellent and shows that once the computer has learned which are the characteristic traits, it can recognise and separate the years of build-up and decay of Chandler Wobble quite well using those traits alone.

It may, however, also be possible to discriminate between G_1 and G_2 years even if the questions were based on spurious data or random answers. In a control experiment we ran the entire program, including the preliminary one-dimensional survey, with spurious data obtained simply by reversing the time sequence of the actual data, that is, the substitution of 1964 for 1901 and so on, in obtaining answers to the questionnaire (Table 1). For the same K constants used with real data,

Table 1 Questions posed for pattern recognition

1 In the preceding 5th, 4th, or 3rd year WTAEO* $\geqslant 1.0$ EM-8† in the New Guinea–New Hebrides region? (Seismicity data from ref.10 and L. Knopoff, unpublished.)
2 In the following 0th, 1st, 2nd year WTAEO $\geqslant 1.0$ EM-8 in the New Guinea–New Hebrides region?
3 In the following 0th, 1st, 2nd, 3rd, or 4th year WTAEO $\geqslant 0.5$ EM-8 in the Tonga–Kermadec region?
4 In the preceding 2nd, 1st, or 0th year WTAEO > 1.5 EM-8 in the Kurile–Japan–Mariana region?
5 In the preceding 1st, 0th or following 1st year WTAEO > 2.0 EM-8 in the Peru–Chile region?
6 In the preceding 3rd, 2nd, 1st, 0th or following 1st year WTAEO > 1.0 EM-8 in central America?
7 In the preceding 2nd, 1st or 0th year WTAEO > 0.8 EM-8 in Java?
8 In the following 0th, 1st, 2nd, 3rd, or 4th year WTAEO > 1.5 EM-8 in the Ryukyu–Philippines region?
9 In the following 0th, 1st, 2nd, 3rd, or 4th year WTAEO > 0.5 EM-8 in the San Andreas–Gorda Ridge region?
10 In the preceding 2nd, 1st, 0th, or following 1st or 2nd year WTAEO > 0.5 EM-8 in China?
11 In the preceding 2nd, 1st, or 0th yar WTAEO > 0.5 EM-8 in the Aleutians?
12 In the preceding 1st, 0th, or following 1st year WTAEO > 0.5 EM-8 along a continent–continent collision zone?
13 In the preceding 5th, 4th, 3rd, 2nd, 1st, 0th, or following 1st year WTAEO > 0.5 EM-8 in the Caribbean?
14 In the preceding 1st, 0th, or following 1st year were there > 15.0 EM-8 integrated over the whole Earth?
15 In the preceding 7th, 6th, 5th, 4th, 3rd, 2nd, or 1st year was there a change in the absolute value of Earth's rotational acceleration ($|\dot{\omega}/\omega|$) of $> 2 \times 10^{-9}$ in units $\Delta\omega/\omega$ yr^{-1} (ref. 11)?
16 In the present year was the absolute value of |the magnitude of Earth's rotational acceleration ($|\dot{\omega}/\omega|$) $< 1.0 \times 10^{-9}$ in units $\Delta\omega/\omega$ yr^{-1}?
17 In the present year was the Earth's rotational acceleration negative?
18 In the present year was the length of day (l.o.d.) more than 0.5 ms longer than the mean value (corrected for secular slowdown)[11]?
19 In the following 2nd year was the speed (v) of the westward drift of the eccentric geomagnetic dipole > 0.25 degrees yr^{-1} (ref. 5)?
20 In the following 3rd or 4th year was the acceleration ($\dot{v}$) of the eccentric geomagnetic dipole motion negative?
21 In the preceding 1st year was the second derivative of the squared amplitude of the Chandler Wobble positive?
22 In the preceding 5th, 4th, or 3rd year was there a major volcanic eruption on Earth (as defined in ref. 12)?

*WTAEO means 'was there an event of'.
†EM-8 signifies a measure of seismicity in units of equivalent magnitude 8 earthquakes, obtained by dividing the cumulative, annual seismic moment released in a region by the seismic moment for a magnitude 8 earthquake.

G_2 characteristic traits could not be found. Only by relaxing the K constants could we obtain a separation of G_1 and G_2 years as measured by the netvote, and even then more years were misidentified than was the case for real data.

Moreover, the traits based on the spurious data did not assemble into coherent hypotheses relating seismicity, Earth rotation and geomagnetic field drift as did the real data. It is, therefore, reasonable to expect that the characteristic traits found with real data may carry physical information, although we cannot prove this.

To test the relationship between earthquake activity and Chandler Wobble excitation a pattern recognition run was made using the first 14 questions only. Questions 1–13 refer to earthquakes in individual seismic belts and Question 14 is a measure of world seismicity. Table 2 shows the traits characteristic of G_1 years of increasing Chandler Wobble amplitudes. Table 3 shows the characteristic traits for G_2 years of declining Chandler Wobble amplitudes. The striking pattern which emerges is that 11 of the 13 seismic belts show either major earthquake activity associated with years of increasing amplitudes or no activity for years of decreasing amplitudes. The

*Columns describe activity in seismic belts (1 = yes, 0 = no); rows are combinations of answers which form individual traits.

Kurile–Japan–Mariana belt and China are the two exceptions. G_1 characteristic traits occur with earthquake activity as a feature (as defined by the questions) in any one of the following seismic belts: central America, Peru–Chile, Tonga–Kermadec, New Guinea–New Hebrides and the Caribbean. Other G_1 traits require earthquakes in two or three belts. World seismicity does not show up by itself as a G_1 trait. These results imply a preferential excitation of the wobble by earthquakes in certain places (defined by latitude, longitude, fault and slip orientation)[1]. The surprising exception of the Japanese and Chinese region is a puzzle; perhaps slow deformation occurs in these belts during aseismic periods many years before or after major earthquakes. Perhaps some unknown compensatory mechanism is at work in these regions which counteracts the effect of earthquakes elsewhere. It seems that the overall pattern indicates that the excitation of the Chandler Wobble is related to earthquakes in specific places. The effect of seismic activity extends over several years before and after (mostly before) the year being tested; an expected result since the Chandler Wobble data were smoothed by taking 6-yr running averages.

The pattern recognition run for all 22 questions produced the characteristic traits shown in Figs 1 and 2. The display in

Fig. 1 Display of 8 G_1 traits associated with years in which amplitudes of the Chandler Wobble are increasing. The component features of each trait are shown in boxes in the proper time sequence with respect to a G_1 year. The number of the question (Table 1) from which the feature is derived is given in each box as an aid to the abbreviations. Eq, Earthquake; l.o.d., length of day.

these figures is organised to show both the time relationships and the way in which questions combine to form traits. Each trait is shown in a vertical column as a triplet or doublet of answers to questions; no singlets emerged as characteristic traits in this study. The vertical position of an answer reflects the time lag or advance in years with respect to the year being tested, which gave the best separation between G_1 and G_2 years in the preliminary one-dimensional survey mentioned earlier.

A dominant feature which emerges for G_1 years is the small value of rotational acceleration (characteristic traits 1, 5, 7, 8). The Earth does not seem to undergo accelerations or decelerations in its rotational velocity, ω, during years of increasing amplitude in the Chandler Wobble and associated increases of seismicity. Trait 7 implies a drop in the rotational acceleration during the years before a G_1 year, to the small values of $\dot{\omega}/\omega$ that go with such a year. This suggests a transition from an earlier G_2 cycle when $\dot{\omega}/\omega$ is large. Association with seismicity occurs, as discussed here, although fewer seismic belts are involved because features not involving earthquakes are now available to make up the quota of traits.

The characteristic traits for the G_2 years of decaying Chandler Wobble amplitudes show an absence of seismicity (traits 1–6). The Earth's rotational acceleration is large in G_2 years (traits 3, 4, 6, 7). Trait 7 identifies a period of volcanic activity ending two years before G_2 years with large values of rotational acceleration. Perhaps the climatic changes induced by volcanic

dust lead to zonal wind changes which perturb the rotational velocity[7]; however, this trait occurs in association with G_2 years when seismicity is low in 11 out of 13 earthquake belts. G_2 traits 4, 6, and 8 describe a pattern in which a large change in rotational velocity occurs near a time when the westward drift is slow; this is followed by a speed-up in the westward drift of the eccentric geomagnetic dipole 3–5 yr later. Therefore, the fast but slowing drift associated with G_1 years (G_1 traits 2, 3, 4 and 6) may be a relic of that acceleration in drift in a preceding G_2 period. The algorithm seems to have recognised the well known lag of several years between the changes in the length of the day and the motion of the eccentric dipole, which has generally been interpreted[5,6] as the time required for the magnetic fluctuation to diffuse through the mantle.

Hypothesis based on pattern recognition

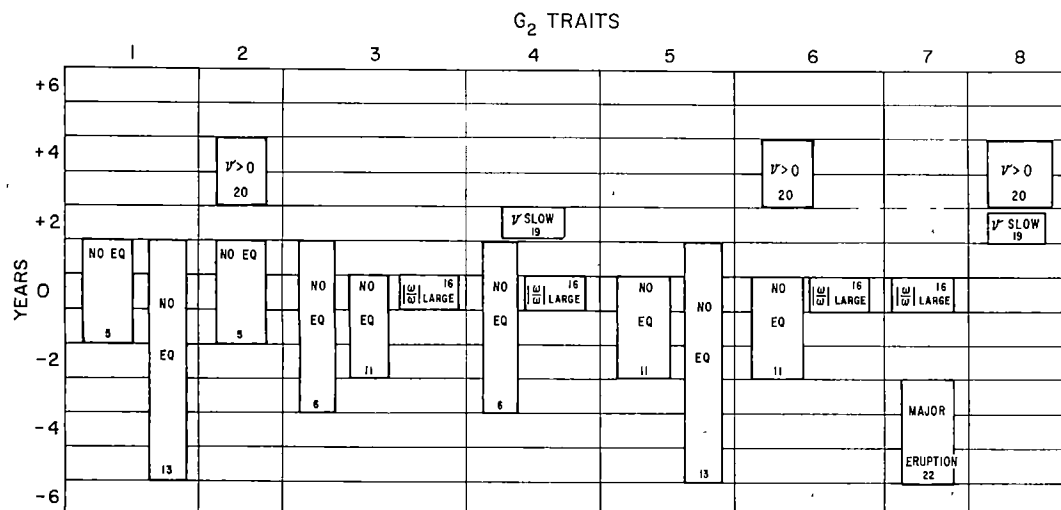
Although we cannot prove that the traits individually or collectively carry significant information, the patterns that emerge invite speculation. In this vein we propose the following hypothesis. Seismic activity in particular belts is associated with displacements of lithospheric plates, which are sufficient to excite the Chandler Wobble. The displacements for these particular earthquakes include as a component large preseismic and postseismic deformation. In a subsequent seismically inactive period the Chandler Wobble decays by a transfer o.


Fig. 2 Display of eight traits associated with years in which amplitudes of the Chandler Wobble are decreasing. Abbreviations as in Fig. 1.

angular momentum to the Earth's fluid core. The core motions produce compensatory changes in the rotation of the Earth, conserving angular momentum. The motions in the core also perturb the geomagnetic field, which becomes evident on the surface after several years of diffusion through the mantle.

The location of the energy sink for the Chandler Wobble is a subject of considerable speculation[13]. The notion that emerges from pattern recognition, that the wobble is damped by a transfer of its angular momentum to the core, should be analysed quantitatively for feasibility. Perhaps a non-spherical or bumpy core–mantle interface facilitates the transfer. Pattern recognition indicates that tectonic movements excite the wobble. The proposal that both may have a common cause cannot be ruled out, although its acceptance is unnecessary now that slow deformation and seismic slip in combination seem sufficient to excite the wobble.

This study was supported by the US Geological Survey, Department of the Interior. We are grateful to I. M. Gelfand, Sh. A. Guberman, and V. I. Keilis-Borok for making the

pattern recognition algorithm available to us. W. H. Press suggested that a spurious data test using time-reversed data was more convincing than one based on an answer matrix with random answers.

A-Protein gene of bacteriophage MS2

W. Fiers, R. Contreras, F. Duerinck, G. Haegmean, J. Merregaert, W. Min Jou, A. Raeymakers, G. Volckaert & M. Ysebaert
Laboratory of Molecular Biology,

J. Van de Kerckhove, F. Nolf & M. Van Montagu
Laboratory of Histology and Genetics, State University of Ghent, Ledeganckstr. 35, B—9000 Ghent, Belgium.

The nucleotide sequence of the A-protein gene of bacteriophage MS2 has been determined and a model for its secondary structure is proposed. Also the amino acid sequence of the A-protein has been almost completely elucidated.

BACTERIOPHAGE MS2, and the closely related R17 and f2, contain three genes coding for the A-protein, the coat protein and the RNA polymerase subunit[1,2]. The first gene is located 5'-proximal[3]. The A-protein contains five histine residues, whereas the coat contains none[4]. It has a molecular weight of 38,000–42,000 and is present in one copy per virion[5–7]. A-protein is required for proper encapsidation as infection with an amber A-mutant in non-permissive conditions leads to production of non-infectious particles, which have a normal shell of coat protein, but from which part of the viral RNA 'dangles' out[8–10]. Selective removal of A-protein by high salt treatment of the virions correlates closely with loss of viability[11]. Although in a normal infection the A-protein enters the host cell together with the RNA and may have a role in the early cytoplasmic events[12,13], it is apparently not absolutely essential as free viral RNA is infectious in a spheroplast system[14].

In R17 the A-protein gene starts with A–U–G and the nucleotide sequence of the surrounding ribosome binding region has been elucidated[15]. We have shown that MS2 RNA starts with a 129-nucleotide long untranslatable leader sequence[16,17] and that the initiation codon of the A-protein gene is G–U–G (ref. 18). The termination signal is U–A–G and in su+am strains partial read-through occurs[7]. We have reported previously the last 135 nucleotides of the A-protein gene and have shown that the latter is followed by an intercistronic region 26 nucleotides long[19]. Some internal segments both of the

R17 and of the MS2 A-protein gene have also been published[20–24], as was the carboxyl-terminal amino acid sequence of the A-protein[25].

Now the complete nucleotide sequence of the A-protein gene has been determined. Also presented in this paper is a tentative model of the secondary structure. Moreover, in an independent effort the amino acid sequence of the MS2 A-protein itself has been almost completely elucidated.

Nucleotide sequence determination

By virtue of its specific secondary and tertiary structure highly ^{32}P-labelled MS2 RNA can be partially digested with RNase T_1 to yield discrete products[26,27]. Such a partial digest was first fractionated by electrophoresis on neutral polyacrylamide gel slabs and the resulting bands were further resolved into individual, pure fragments by two-dimensional gel electrophoresis[17,28]. These fragments were of chain length 25–250 and generally adequate for complete sequencing according to the methods developed by Sanger[29] or some modifications thereof[17,24,30]. Several fragments were often found to be related to each other (for example, one containing an extension of the other) and hence were derived from the same region of the RNA molecule; these related fragments are called a family. Many families could be identified by the presence of a unique T_1-oligonucleotide, like A–A–C–A–G or U–A–A–A–G (occurring once in MS2 RNA).

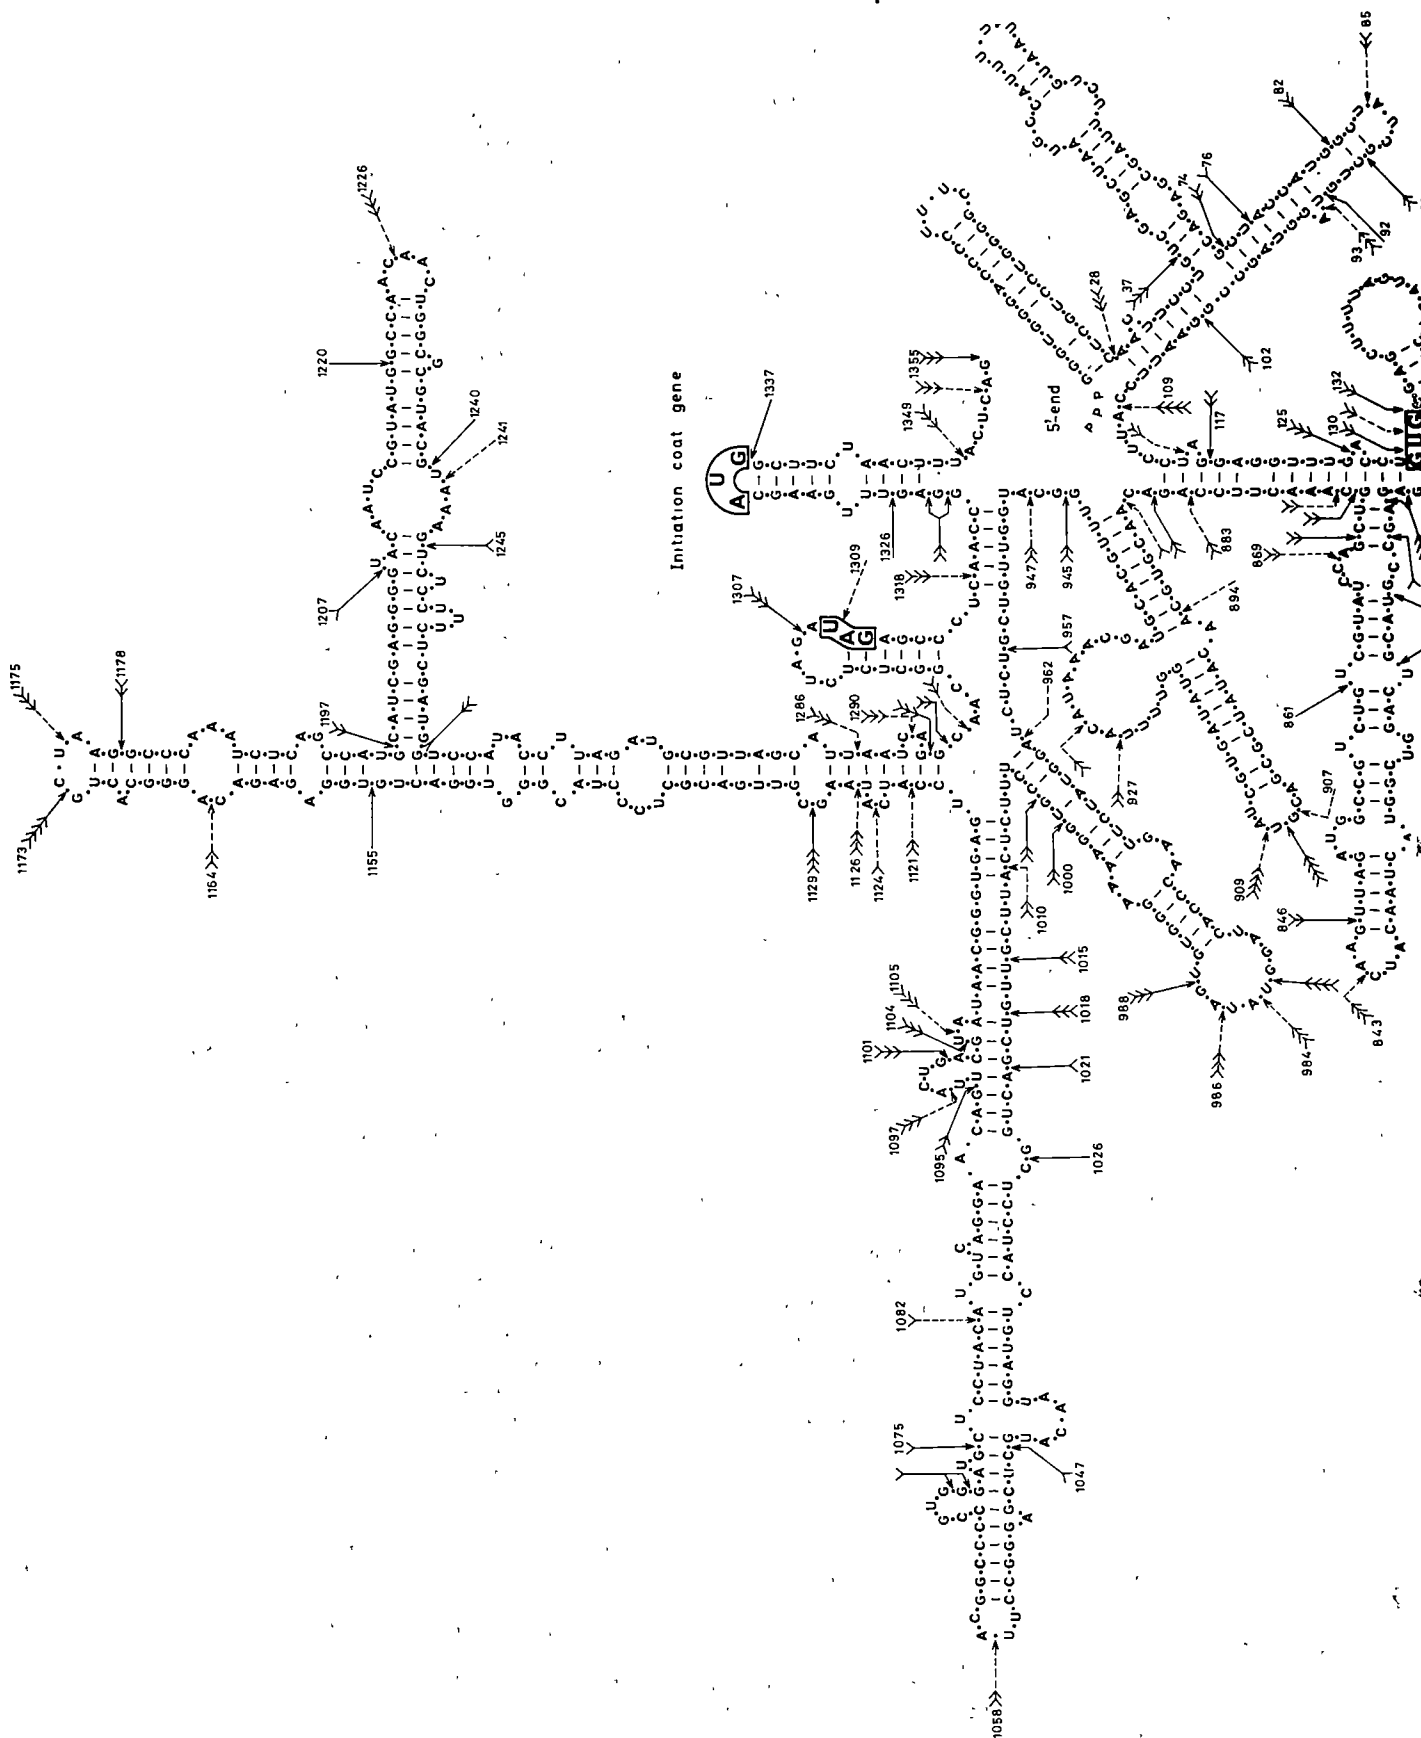
Some polypurine tracts have previously been located in the 5'-third of MS2 RNA[31] and on this basis some families could be assigned to the A-protein gene. Very mild T_1 digests, followed by separation on a 4% polyacrylamide gel, allowed the isolation of fragments in the size range of 200–1,000 nucleotides. In this


Fig. 1 Secondary structure model of the MS2 RNA nucleotide sequence up to position 1,355. Starting from the 5'-end the sequence contains the leader sequence, the A-protein gene, the first intercistronic region and the coat protein gene (only the beginning is shown here; the further sequence is given in ref. 48). The initiation signal G–U–G of the A-protein gene, the termination signal U–A–G, and the initiation signal A–U–G of the coat gene are shown in boxes. Full arrows indicate splitting points by RNase T₁ under conditions of partial digestion, and dashed arrows likewise indicate sites cleaved by carboxymethylated RNase (ref. 32). The feathers on the arrows are a measure of the susceptibility of the site; for example, four feather arrows indicate sites which are always cleaved, even under the mildest conditions used. The numbers refer to the nucleotides.

Fig. 2 Nucleotide sequence and amino acid sequence of the A-protein gene. Full lines indicate chymotrypsin peptides, dashed lines trypsin peptides and pointed lines thermolysin peptides; all these were completely sequenced. Also indicated are the out-of-phase termination signals. The number of nucleotides (from the 5'-end) are shown at the left and the number of amino acids at the right.

way all families belonging to the A-protein gene could be identified and roughly ordered. Unambiguous overlaps, however, were established by partial digestion of MS2 RNA with carboxymethylated (CM) ribonuclease[32]; this enzyme cleaves mainly C–A and U–A bonds. The CM partial digests of total MS2 RNA were fractionated in the same way as the T_1 digests. The resulting CM fragments not only provided all the required overlaps, but also allowed to sequence some regions which were represented in poor yield in the set of T_1 fragments.

For example the T_1 fragments 133–366 (positions are given in nucleotide units) and 367–632 were characterised. The former could be linked to the 5'-end[16-18] by virtue of the CM fragment 110–261, which a.o. contains the unique reference oligonucleotide A–G–G–A–G–G–U. Both T_1 fragments could then be linked by the CM fragment 339–433. Another CM fragment, 601–700 overlapped the second and the third T_1 family and so on. The detailed derivation of the nucleotide sequence will be reported elsewhere.

The nucleotide sequence of the A-protein gene, together with the preceding 5'-leader sequence and the succeeding link to the coat protein gene is presented in Fig. 1 in the form of a secondary structure model. The latter is partly based on experimental evidence, such as segments which fractionate together unless denaturing conditions are used, and susceptibility of sites to cleavage by the largely single-strand specific T_1 or CM RNases. Furthermore the thermodynamic stability of alternative configurations can be estimated[33] and on this basis the stability of the secondary structure model can be maximised. These estimates, however, involve many uncertainties. Moreover, the structure is certainly further moulded by tertiary interactions, as have been identified in tRNA (ref. 34). For these reasons the model shown in Fig. 1 should be regarded as tentative.

Amino acid sequence

Pure MS2 A-protein was obtained by isolation of the A-protein–RNA complex according to Osborn *et al.*[35], phenolisation, chromatography on a Sephadex G-200 column in the presence of 1% sodium dodecyl sulphate (SDS) and further separation by preparative polyacrylamide electrophoresis in the presence

of SDS. Starting from 5 g of virus 25 mg A-protein was obtained. The carboxymethylated A-protein was digested with appropriate proteolytic enzymes. The soluble peptides were fractionated by gel filtration on Sephadex G-25 in 5% formic acid followed by a three-dimensional combination of electrophoresis and paper chromatography[36]. Peptides were detected with fluorescamine and characterised by the micro dansyl-Edman procedure[37]. Several "insoluble" peptides were labelled with fluorescamine[38] and purified by electrophoresis in the presence of SDS on 17.5% polyacrylamide gel. The results of the amino acid sequence determination are summarised in Fig. 2. Further methodological details will be published elsewhere. Note that the first seven amino acids and the last three were determined on the complete polypeptide.

Except for a few gaps and missing overlaps, the amino acid sequence can be reconstructed without reference to the nucleotide sequence. It is in total agreement with the amino acid sequence derived from the nucleotide sequence on the basis of the known universal genetic code. Occasional apparent discrepancies were encountered, for example a threonine in position 245. But analysis of the same virus stock as used for nucleotide sequence analysis revealed the presence of serine at this position.

Biological implications

As previously discussed[18], the MS2 A-protein gene starts with G–U–G. Although more than 10 ribosome binding regions have been identified so far in phage and bacterial messengers[2,39] all other normal initiation codons are A–U–G (G–U–G, however, seems to be a functional start codon in translational reinitiation[40]). The initiation site of the R17 A-protein gene contains also A–U–G (ref. 15), in spite of the fact that the sequence of the region is otherwise identical to that of MS2 and that the level of gene expression is approximately the same in the two phages. The starting methionine residue is not removed after biosynthesis; the same is true for the analogous sequence Met–Arg–Val ... of the UDP galactose 4-epimerase[41]. The first eight amino acids of R17 have previously been determined[42]; they are identical except for a Thr→Ala change.

The code words used in the A-protein message are summarised in Fig. 3. Except for U–G–U (which does occur in the coat protein gene) all sense codons are found in the A-protein gene. It is quite possible that protein synthesis is also regulated at the level of chain elongation rate and this could be due to modulating codons which would locally brake the speed of the ribosomes. Therefore the latter type of codons would be avoided in a gene expressed at high frequency such as the coat protein gene. Candidates for such a modulating function are a.o. A–U–A, A–G–A and A–G–G. One may also note that for

Fig. 3 Code words used in the A-protein gene. The frequency of occurrence of each code word is given. ⊙, Initiation codon; ○, termination codon. Numbers encircled indicate codons not used in the coat gene; note that the coat protein does not contain histidine.

some amino acids (Ile, Asn, Gly) one degenerate codon is much preferred over the other (Fig. 3). The secondary folding of the viral RNA is certainly very important both from a functional and from a structural point of view. Yet it is not evident whether degeneracy of the code plays a role in this respect; in the model of the A-protein gene (Fig. 1), 67.4% of all the nucleotides are involved in secondary interactions, while for third letters this amounts to 68.4%, that is only slightly higher. The occurrence of termination signals in the two illegitimate reading frames (Fig. 2) is about as expected from a random distribution.

The ribosome binding region of the A-protein gene is only accessible after partial degradation and loss of three-dimensional folding of the viral RNA (ref. 43). It has been proposed that this gene is expressed on chains *statu nascendi* and turned off on subsequent folding of the viral RNA[2,44,45]. We have experimental evidence which supports this hypothesis. This model of auto-control at a translational level can be explained on the basis of the secondary structure (Fig. 1). When nearly two-thirds of the A-gene has been synthesised, a region appears (874–885) which interacts with part of the ribosome binding region and in this way closes off access to the latter. Further information is required, however, to prove this structure–function relationship.

Sixty to seventy per cent of all MS2 amber mutants are affected in the A-protein gene[46]. There are 18 glutamine residues in the A-protein, of which nine are coded by C–A–G (most amber mutations are C–A–G→U–A–G transitions). Yet more than one-third of the A-protein amber mutations occur at a

single site, resulting in non-permissive conditions in a polypeptide 88% of full length[47]. This mutational hot spot corresponds to the C–A–G at position 1,164–1,166 (Fig. 1); obviously it is rather exposed and therefore easily accessible to mutagenic reagents. A similar conclusion has previously been made for the mutation-prone C–A–G codons in the coat gene[48].

Compared with the coat protein the A-protein has a higher leucine to isoleucine ratio (factor 2.6), a higher tryptophan content (factor 2.0) and in particular a higher arginine content (factor 2.4). The abundant arginine residues (for example, in regions 168–177 185–195 and 388–393) may account for the strong binding to the RNA. Indeed the interactions between the A-protein and the other components of the virion are salt sensitive[11]. Also some clustering of hydrophobic amino acids is observed (such as the regions 196–206, 261–267 and 272–303) and this may explain the general stickiness of the A-protein. It is conceivable that during the formation of the capsid a single coat protein molecule (out of the 180) is replaced by an A-protein molecule. There are no regions with extensive sequence homology in these two molecules however.

Late Miocene sediments and fossils from the Northern Kenya Rift Valley

M. Pickford

Department of Geology, Queen Mary College, University of London, UK

The Lukeino Formation occurs within a long sequence of Neogene sedimentary units that are soundly calibrated by K–Ar dates. It has yielded an abundant and varied fauna and flora, and contains a wealth of information on palaeoenvironments and sedimentary processes occurring during its deposition. Previously unpublished vertebrate and invertebrate assemblages, about 6.5 Myr old, are recorded here, and the stratigraphic and sedimentary framework of the formation is established.

THE Lukeino Formation was mapped during 1973 as part of the programme dealing with all the sedimentary units in the Baringo area, Kenya, based at Bedford College, London, under Professor W. W. Bishop[1]. This work has resulted in the elucidation of the geographic extent, stratigraphic succession, facies changes, palaeoenvironments and palaeogeomorphological setting of the basin. During the survey many vertebrate and invertebrate fossils were collected including the crown of a hominid molar. Mapping has also shown that fossils collected previously from the Kaperyon area actually came from the Lukeino Formation. The Lukeino Formation was examined cursorily by Bishop et al.[1] in 1971, and this paper, apart from recording numerous new faunal elements, discusses in detail the sediments themselves.

Lukeino Formation

The Lukeino Formation (Figs 1–3) is composed of up to 130 m of primary and reworked volcanic rock. The sediments were deposited in a basin floored by the Kabarnet Trachyte Formation[2] and are overlain by the Kaparaina Basalt Formation[3]. Three sills have intruded the formation.

Fig. 2   Type section of Lukeino Formation at Kobuluk.

The Lukeino unit is given formational status because it is clearly not part of the Kaparaina Basalt Formation in which it was originally included[1]. The maximum observed thickness occurs at Kobuluk (section K–K', Fig. 1) north of Yatya (0°52'30"N, 35°54'30"E) where 130 m of sediments are seen in an incomplete but continuous section. The base of the formation is not exposed in this area and the top was eroded before extrusion of the lowest local flow of Kaparaina Basalt. Extrapolation along strike suggests, however, that little is missing from the Kobuluk section. Poor exposure over much of the remaining outcrop of the Lukeino Formation has severely hampered stratigraphic study but the general relationships have been deciphered. Four members are recognised in the formation (A to D, Fig. 2).

A (15 m) is composed predominantly of red sediment but contains pale orange and yellow tuffaceous horizons. Occasional sand and grit-filled channels occur from which various fossils have been obtained including a hominid molar. Much of the epiclastic material is derived from ferruginous weathering products of the Kabarnet Trachyte. Varying amounts of pyroclastic material, possibly from contemporary volcanic sources as well as from the underlying Mpesida Beds[1], are mixed with the derived weathering products. The red beds seem to contain marginal lacustrine deposits as indicated by the presence of algal mats and lacustrine bivalves (including complete specimens with valves in the closed position).

The central and northern parts of B (50 m) consist of diatomaceous and pale cream silty tuffs, giving way southwards to red beds similar to those of A.

Well-bedded, grey, sandy and silty lapilli tuffs form a widespread Member C (12 m). They may be an extension northwards of the Riwo Beds of Martyn[4] which outcrop east of Kabarnet, about 35 km south-west of Yatya. The tuffs in the northern exposures contain a variety of lacustrine molluscs, while in the south they have yielded a few mammal bones. They are in general poorly fossiliferous.

Diatomaceous and silty tuffs comprise the major portion of Member D (35 m). Minor amounts of pumice tuff occur in the sequence except in the Kobuluk River, 2 km north of Kobuluk section, where a very thick succession of tuffs, agglomerates and breccias indicates proximity to a volcanic centre (Fig. 4). Away from the centre there are widespread fine-grained diatomaceous silts and tuffs which in places are exceptionally rich in fish impressions.

In the central parts of the basin, an extensive silty tuff outcrops in the diatomaceous sequence. The remarkable aspect of this unit is its 'intrusive' appearance. Its upper surface has many structures usually associated with igneous intrusions, such as cross cutting, stoping and distortion of bedding, but no baking was seen. This unit extends at least 12 km from north to south. Close examination shows that it is made up of small fragments of pre-existing sediments, sometimes well-laminated and it seems to represent a remobilised tuff. The intrusive nature of the contacts

possibly results from slumping of an unconsolidated stratum, accompanied by rupturing of overlying and underlying laminated diatomaceous tuffs.

Sills

Three sills have intruded the Lukeino Formation, two of which were emplaced before the deposition of Member D. The lowermost of these (The Rormuch Sill) is a coarse porphyritic dolerite with a fine-grained matrix. Honey-coloured feldspar phenocrysts up to 2 cm long are scattered throughout the sill, but become smaller northwards Intrusive contacts are displayed in several outcrops. The second sill (the Kobuluk Sill) is finer grained than the Rormuch Sill, and contains olivine phenocrysts up to 2 mm long set in a fine-grained grey matrix. The upper parts of this unit are often vesicular. The upper surface of this sill is often flow-banded and possesses pressure ridges, reminiscent of ropy lava, but its intrusive character is indicated in several outcrops. Fragments of both sills are found in the agglomerates of the Kobuluk River volcanic centre, which must therefore postdate the emplacement of the sills.

The third sill (the Cheseton Sill) has intruded sediments overlying tuffs and agglomerates of the Kobuluk River volcanic centre. It is very fine grained with occasional feldspar phenocrysts and indeed resembles a basalt flow. Its intrusive nature is indicated by a glassy upper surface, baked overlying sediments and the observation that it changes horizon.

Post-Lukeino times

Relative uplift of the Lukeino area after the deposition of Member D resulted in erosion of the formation, and in places valleys were cut through the sediments to the underlying Kabarnet Trachyte. The eroding landscape was eventually capped by basalts of the Kaparaina Formation, although in the north the basalts are now absent and the Lukeino Formation is overlain unconformably by sediments of the Chemeron Formation (Fig. 3 and ref. 5). The northern part of the Lukeino Block may not have been covered by Kaparaina Basalt, a suggestion prompted by thinning of the Basalts and a decrease in the number of flows northwards.

Palaeogeomorphology and palaeoenvironments

Fig 4 shows the palaeoenvironments and facies distribution in the Lukeino Formation. The Lukeino basin was initiated as a result of tectonic activity along the Kito Pass, Sumet 'B' and Saimo faults (Fig. 1) which formed the western boundary against which the sediments were ponded. The large mountain mass of Tiati volcano to the north was the probable northern bounding feature (Fig. 1). The Lukeino sediments are still relatively thick where they disappear under the Ribkwo Trachyte in the north of the area. To the south the sediments are obscured under an extensive pile of Kaparaina Basalt. To the east the sediments are downfaulted and covered by up to 280 m of Kaparaina

Fig. 3 North–south section through the Lukeino Formation. In the south Lukeino Formation sediment is overlain by Kaparaina Basalt, which in turn is overlain by Chemeron Formation sediment. In the north the Chemeron Formation oversteps the Lukeino Formation. A—E refer to localities indicated in Fig. 1.
Fig. 4 Palaeoenvironments and facies distribution of the Lukeino Formation.

Basalt. The formation is exposed over an area of about 450 km² but outcrop is not continuous (Fig. 1). Sediments were derived from north, east and south, as well as from the growing Tugen Hills to the west and the Kobuluk River volcano within the basin. Much of the basal and lake margin sediment is red, and by analogy with present-day conditions, seems to be reworked from soils developed on the Kabarnet Trachyte. Algal limestones found in the red bed sequence suggest a lake marginal setting.

The grey tuffaceous sediments of Member C seem to be lacustrine in the north where they are well bedded and contain lacustrine gastropods and bivalves. In the south they are more massive, coarser and contain weathered horizons attest to emergence during Member D times, but the tuff.

Sediments of Member D were deposited in lacustrine conditions. The central parts of the basin contain abundant fish and plant remains in paper shales. Grass, leaves and diatoms (*Melosira* sp. and others) occur with cyprinids and cichlids. The fish are very abundant and scattered along bedding planes in the paper shales. Occasional suncracked horizons attest to emergence during Member D times, but these horizons are not close stratigraphically to the fish localities.

Fauna and flora

The list of fauna collected from the Lukeino Formation (including the original Kaperyon[1] collections) is shown in Table 1. Fossils were recovered from 47 localities, most of which occur in Members A and B. Fossil plants include leaves, wood, grass, ferns and diatoms. Algae are common, usually occurring as algal mats. Many of the specimens await detailed study, but several additions have been made to the existing list[1].

Hippopotamidae make up a large proportion of the artiodactyl assemblage while bovids, suids and giraffids are scarce. This is probably a reflection of the lacustrine and lake marginal nature of the sediments. The lake was probably always fresh or weakly saline as indicated by the

molluscs, diatoms, algae and fish. Crocodiles are common, and at least two species are present (the nile crocodile and a new species of broadnosed crocodile (Tchernov, personal communication)).

Maglio[8,9] has expressed some concern over the anomalous appearance of two species of Proboscidea collected from a locality mapped as Kaperyon Formation[1]. Remapping has now shown that the Kaperyon Formation is composed of three separate bodies. The Proboscidea referred to above come from sediments of the Lukeino Formation and are about 1.5 Myr older than originally thought. This is in keeping with the broad 'stage of evolution' age assigned to them by Maglio.

Age

The Lukeino Formation unconformably overlies the Kabarnet Trachyte Formation from which K–Ar dates of 7.2 ± 0.3, 6.8 ± 0.2 and 6.7 ± 0.3 Myr have been obtained[1]. They are uncomfortably overlain by the Kaparaina Basalt Formation from which a single date of 5.4 ± 0.2 Myr has been obtained[1]. The sediments were probably deposited about 6.5 Myr ago. Continued subsidence east of the Tugen Hills since deposition of the Ngorora Formation[10] (between 12 Myr and 9 Myr) resulted in several periods of sediment deposition[1]. The Lukeino episode covers a period about which little is known south of the Sahara, and its position in a well calibrated sequence enhances its importance.

Hominid molar

A lower molar (Fig. 5), clearly hominoid in structure, was found a few feet from outcrops of a 0.5 m thick, pink sandy and gritty horizon with pyrolusite and ferruginous staining and concretions. The horizon lies in the middle portion of Member A at Chepboit (locality 2/219) 5.5 km west of Yatya.

At the discovery site, fossils are concentrated in the coarse basal 10 cm in which ferruginous concretions and scarlet pebbles are common. The colour of the hominid molar closely resembles that of teeth found *in situ* in the

basal layer. Furthermore the tooth is slightly rolled and the roots have been dissolved away in a similar fashion to teeth found *in situ* in the grit. It is also slightly stained by pyrolusite and has a small pyrolusite concretion stuck to it. Dr P. Andrews (British Museum, Natural History) supplied the following description of the tooth.

"KNM LU335 is a left lower molar of an hominoid
Fig. 5   KNM LU335, left lower molar, Hominidae indet.

primate. The crown was probably unerupted, and there is no sign of root development. The occlusal surface of the crown is intact but slightly pitted by weathering in places, and the base of the crown is slightly eroded so that nowhere is the basal limit present. The crown is short and broad : mesiodistal (md) length is 11.4 mm and buccolingual (bl) breadth 10.6 mm and the breadth/length index (bl/md × 100) is 93%. Talonid breadth and trigonid breadth are the same. The cusps are low and rounded, particularly the protoconid and hypoconid. The trigonid basin is small but quite deep. It is set well back from the low mesial marginal ridge of the crown and is bounded distally by a low transverse ridge connecting protoconid and metaconid. The talonid basin is small and crowded by the talonid cusps, so much so that the width of the basin is only half that of the total crown width. The length of the talonid basin is approximately equal to the lengths of the trigonid basin and distal fovea put together. The hypoconulid is placed buccal to the midline of the crown to a degree more often seen in M_2 than in M_1 in hominoid lower molars. The distal fovea is a deep pit distal to the low rounded hypoconulid-entoconid ridge which is cut by a very narrow groove connecting the distal fovea with the talonid basin. The groove system of the occlusal surface has a dryopithecine Y configuration. The buccal main groove and the buccal distal groove are particularly distinct, running between the buccal cusps to end in small pits on the remnants of the buccal cingulum, in the interval between cusps. Elsewhere the grooves are partly obscured by the secondary wrinkling which is most strongly developed in the talonid basin. Enamel thickness is very great.

Whether it is M_1 or M_2, KNM LU335 is considerably smaller than any of the australopithecines, *sensu lato*. It is closest in general dimensions to the M_2 of the chimpanzee. In morphology the Lukeino specimen is remarkably similar to the M_1 of robust australopithecines[6]. The most characteristic feature of the crown, and contributing to its breadth, is the lateral flare of its buccal edge. Since there are also faint traces of a buccal cingulum at the bases of the buccal grooves, it seems very likely that the lateral flare is formed as a result of incorporation of the cingulum into the occlusal surface of the crown, a process that in this tooth is not quite complete. The same feature is present in the hominoid upper molar from Ngorora[7] which is also low crowned, has a marked lingual flare, and has faint traces of a lingual cingulum.

Another feature of the Lukeino lower molar is the

approximately equal division of the crown into central (talonid) and mesial/distal basins. The protocone of the upper molar occludes with the talonid basin, and the hypocone with the basin constituted by the distal fovea of the equivalent lower molar and the trigonid basin of the lower molar next in line. The equal division of the lower molar crown into these two occlusal basins indicates that the upper molar had approximately equal sized protocone and hypocone. This is the case with the Ngorora upper molar, but is quite different from most dryopithecines, in which the lower molar trigonid basins occupy an insignificant proportion of crown length, the talonid basins occupying up to three quarters of the crown length, and the upper molar protocones are much larger than the hypocones. This pattern seen in dryopithecines is repeated in modern apes and also in *Ramapithecus wickeri* and some australopithecines, but in general hominids have more equally sub-divided lower molars, as in the Lukeino molar. KNM LU335, is thus tentatively included within the Hominidae."

I thank the Ministry of Natural Resources of the Government of Kenya for permission to study in Baringo District;

Noble gases in lava rock from Mount Capulin, New Mexico

E. W. Hennecke & O. K. Manuel

Nuclear Division, Department of Chemistry, University of Missouri, Rolla, Missouri 65401

Noble gases in lava rocks from Mount Capulin crater cone contain 'parentless' ^{40}Ar and xenon trapped from the hot magma. The isotopic composition of the xenon is consistent with a mixture of 90% atmospheric and 10% solar xenon, but no radiogenic ^{129}Xe has been observed. These results do not support an earlier suggestion that radiogenic ^{129}Xe, found in CO_2 gas from this region of New Mexico, had been transported in hot magmas.

THE presence of a relatively large excess of radiogenic ^{129}Xe, the decay product of ^{129}I, has been recorded[1] in CO_2 well-gas from Harding County, New Mexico. The origin of the CO_2 gas is not understood, and the radiogenic ^{129}Xe may have been brought near to the Earth's surface in hot magmas[1,2], where intrusive contact with crustal carbonate rocks produced CO_2, during a phase of recent igneous activity in this region of New Mexico[3]. Reports on the iodine content of limestone[4] and the equilibrium ratio[5] of $^{129}I/^{127}I$ indicate however, that only a negligible fraction ($\approx 10^{-7}$) of the radiogenic ^{129}Xe

in the CO_2 gas could have come from the limestone.

We have already suggested[1] that lava rocks from this region of New Mexico might contain radiogenic ^{129}Xe, provided that xenon in the magma had not completely escaped as the lava cooled or had been diluted by exchange with atmospheric gases. Radiogenic ^{40}Ar can be used as a trace[6,7] to estimate the amount of gas loss from the hot lava, and a comparison of the abundances of trapped noble gases with those in the atmosphere[8,9] can be used to look for equilibration with atmospheric noble gases. We therefore undertook this study to measure the abundance and isotopic composition of the noble gases in a lava rock from this region of New Mexico, using a large specimen (≈ 2 kg) of lava rock from the Mount Capulin crater cone. The age of this cone has been estimated from ^{14}C dating to be between 4,400 and 10,000 years old[10].

The abundances and isotopic compositions were measured in two samples of the lava rock. To minimise surface contamination, the samples were taken from the interior of the specimen and were not crushed before gas extraction. They were mounted in the upper chamber of a water-cooled quartz extraction

The isotopic compositions of atmospheric Ne, Ar, Kr and Xe are from refs 33, 12, 34 and 35, respectively, and the isotopic compositions of solar Ne, Ar, Kr and Xe are from ref. 29.

bottle, the pressure was reduced to about 1×10^{-8} mmHg and the system blank was measured by collecting and analysing the gases generated by heating the empty molybdenum crucible to the highest extraction temperature, about 1,700 °C. After the system blank had been reduced to an acceptable level, the sample was dropped into the degassed crucible and the gases were extracted by stepwise heating. Extraction temperatures of 600 °C, 1,200 °C and 1,700 °C were used for sample I (18.164 g) and 800 °C and 1,700 °C were used for sample II (15.864 g). The samples were maintained at each temperature for 30 min. The gases released at each temperature were cleaned, separated and analysed using procedures described previously[11]. Standard volumes of air (≈ 0.01 cm^3 at standard temperature and pressure —STP) were analysed before and after the analysis of each sample to determine the sensitivity and mass discrimination of the mass spectrometer.

Noble gas abundances

The amounts of noble gases released at each extraction temperature are shown in Table 1, together with the uncertainties in the gas abundance measurements resulting from variations in the sensitivity of the mass spectrometer. The mass spectrometer signals for the 1,700 °C system blanks have been converted to effective gas contents (cm^3 g^{-1}, at STP). The isotopic ratios of the blanks were atmospheric to within ±5%, and blanks at 600, 800, and 1,200 °C were negligible except with ^{4}He when, at 600, 800 and 1,200 °C they were about 0.75 of their value at 1,700 °C. The relatively high blank level for He probably results from the diffusion of He into the glass vacuum system during the extraction and cleaning of gases. The total content of each noble gas, corrected for blanks, is shown in Table 2. In computing the totals we considered only the ^{4}He released at 1,700 °C, since the amounts released at lower temperatures were approximately equal to the ^{4}He blank level. The results of these analyses provide no information on the fraction of ^{4}He which is radiogenic, so we shall denote the concentration thus: (^{4}He).

The amounts of radiogenic ^{40}Ar (^{40r}Ar) were computed by assuming non-radiogenic argon to be of atmospheric composition[12] (Table 1). The average concentration of ^{40r}Ar is 108×10^{-9} cm^3 per gram of lava rock at STP. Decay of ^{40}K during the lifetime of the rock would generate only 28×10^{-9} cm^3 per g of potassium (STP). We interpret this as evidence of incomplete loss of ^{40r}Ar from the magma. These results suggest that radiogenic ^{129}Xe from the magma would also be trapped in the lava rocks, and its detection depends on the extent of dilution by atmospheric xenon.

To look for evidence of exchange of atmospheric noble gases with those in the lava rocks, we compared the abundance pattern of trapped noble gases in the lava rock with that in the atmosphere, using the method of Canalas et al.[13], who defined a fractionation factor, F^m, as

$$F^m = (^mX/^{130}Xe)_{sample}/(^mX/^{130}Xe)_{cosmic} \qquad (1)$$

where ^mX is any noble gas isotope of mass number, m, and cosmic abundances are those given by Suess and Urey[14].

The values of log F^m against mass number are shown in Fig. 1 for noble gases in the lava rocks (Table 1) and in the atmosphere[15]. Relative to the atmospheric abundances of noble gases, the average value of F^m in the lava rocks for ^{84}Kr is lower by a factor of 3, and for ^{22}Ne it is higher by a factor of 15. Within experimental uncertainties, the F^m values of ^{36}Ar and (^{4}He) are identical to those in the atmosphere. The irregular variation of F^m values with m (Fig. 1) does not fit the pattern that could be expected if equilibration with atmospheric gases is attained. Solubility equilibrium of atmospheric gases with the hot magma would have discriminated against the incorporation of large atoms[16], and adsorption equilibrium of atmospheric gases would have discriminated against small atoms[17]. The high Xe/Kr ratios in lava rock cannot be accounted for by the solution of atmospheric xenon in the parent magma, but may have resulted from adsorption.

Fig. 1 Log fractionation factor against mass number. The solid line shows the abundance pattern of noble gases in the atmosphere[15]; ○ noble gases in the Mount Capulin samples.
Fig. 2 A comparison of noble gas ratios in the Mount Capulin samples and in other material. *a*, Ratios expected in rocks which sample atmospheric and cosmic abundances of noble gases; *b*, slope used by Fisher[9,21] and Phinney[18]; ●, coal[13], Murray carbonaceous chrondrite (Mu. ch.)[26], Bruderheim chondrite (Br. ch.)[32], Thailand tektites[8], Mount Capulin lava rocks, and enstaitate melt[16]; ○, shales[13]; ■, basalts[9] from Pacific Seamount and Nigeria; ×, basalts from mid-ocean ridge reported to contain primordial noble gases[29-22]; △, air[15]; ▲, cosmic[14].

Stepwise extraction of gases is useful in separating gases from different sites[8,11], as adsorbed gases are preferentially released at the lower extraction temperatures, and the dissolved gases are enriched in gases released at higher extraction temperatures. Adsorption is highly specific for xenon[18], and the enrichment of xenon in the 600 °C fraction of sample I may result from the release of adsorbed gases. The bulks of all noble gases were, however, retained together with radiogenic ^{40}Ar until the samples were melted at 1,700 °C. As ^{40r}Ar was derived from the magma, the release of this isotope can be considered as a tracer for the release of noble gases incorporated into the rock from the magma. Although we cannot rule out completely the possibility of tenaciously adsorbed xenon being released in the 1,700 °C fraction, high Xe/Kr ratios can be expected in the magma as the results of other studies[13,17,18] indicate that the Xe/Kr ratio in air is anomalously low because of the preferential adsorption of xenon on fine-grained sediments. Since 'parentless' ^{40}Ar came in with the hot magma and is still present in the lava rock, there is an overwhelming probability that any radiogenic ^{129}Xe originally in the hot magma would also still be trapped in the lava rock.

The relatively high values of the Ne/Ar ratios in these lava rocks seem to confirm reports of a high Ne/Ar ratio in pumice[19] and of high Ne/Ar ratios in lava rocks from the sea floor[20]. Although the enrichment of lighter noble gases in the latter rocks has been interpreted as evidence of the presence of primordial rare gases from the Earth's mantle[20-22], it is possible that the enrichment results from the preferential leakage of lightweight atmospheric noble gases into rocks which have low concentrations of indigenous noble gases. Thailand tektites show a large excess of neon[8], but it has been shown,

from the diffusion coefficient of neon in tektite glass[23] and from the Kr–Ar[23,24] and fission track[25] age estimates of those tektites, that the high neon content could result from the diffusion of atmospheric neon into the tektite. The isotopic ratios of Ne and Xe in the atmosphere are quite different from those in meteorites[26] and from that imbedded in lunar fines[27].

Isotopic abundances

The isotopic composition of the noble gases released from Mount Capulin basalt are given in Table 2. No attempt has been made to measure the ^{3}He content, and there have been no corrections for blanks, because most of the isotopic ratios are essentially atmospheric. The isotopic compositions are atmospheric within $\pm 2\sigma$ ($\sigma = 1$ standard deviation), except for an obvious excess of radiogenic ^{40}Ar and perhaps a slight depletion of the heavy xenon isotopes in the 1,700 °C fraction of sample I and a slight enrichment of the light xenon isotopes in the 1,700 °C fraction of sample II.

We could not find radiogenic ^{129}Xe in lava rock from the region where radiogenic ^{129}Xe was found in CO_2 gas; however, the 'parentless' ^{40r}Ar and high Xe/Kr ratios in gases released at the highest extraction temperatures compel us to conclude that the Xe originated in the magma. The absence of radiogenic ^{129}Xe in these samples suggests that radiogenic ^{129}Xe *in the* CO_2 gas may come from some source other than the hot magma, and since it did not come from the decomposition of limestone[1], other origins should be considered. Leakage of CO_2 from an asthenosphere which contains a CO_2-rich liquid phase[28] seems to be a reasonable alternative which could account for both the high CO_2 content of the gas and the presence of the decay product of extinct ^{129}I in gas pockets trapped within the Earth's crust.

The isotopic ratios (Table 2) contain no evidence of solar-type noble gases, except for the slight enrichment of the light Xe isotopes and depletion of the heavy Xe isotopes in the 1,700 °C fractions. A mixture containing atmospheric Xe and solar Xe in the ratio 9:1, could account for the isotopic ratios in Xe released from both samples at 1,700 °C. Because of the very small differences between atmospheric Xe and that released from the Mount Capulin basalt at 1,700 °C, caution should be exercised in interpreting our results as evidence of primitive Xe within the Earth. The isotopic ratios of the lighter noble gases seem to be atmospheric.

Atmospheric or solar origin?

Previous observations cited as evidence that oceanic lava rocks contain primitive gases from the Earth's mantle include the similarity between the relative abundances of noble gases in some lava rocks and in meteorites[20-22], the strong contrast of these relative abundances with those in the atmosphere[20,21], the fact that the simple fractionation of atmospheric noble gases could not simultaneously produce higher values for the Ne/Xe ratio and lower values for the Kr/Xe ratio, and the failure of noble gas ratios in some lava rocks to lie along equilibrium correlation lines defined by Henry constants[16,30] for the solubility of atmospheric noble gases into a melt[20-22].

Fisher[9] first used the correlation of noble gas ratios for ^{36}Ar, Kr, and Xe on log–log plots to differentiate between noble gases from the atmosphere and noble gases from a solar (primordial) source. Subsequently, Dymond and Hogan[20] and Fisher[21] used these plots, and one involving Ne, to show that the noble gas contents in some deep sea lava rocks did not fit the equilibrium correlation line for atmospheric noble gases. For any four noble gases, a, b c, and d, the concentration ratios, C_a/C_b, C_c/C_d, and so on, in a melt at equilibrium with an atmosphere having partial pressures, p_a, p_b, p_c are defined by[9,16,30]

$$\ln(C_a/C_b) - \ln(p_a/p_b) =$$

$$[(r_a^2 - r_b^2)/(r_c^2 - r_d^2)] [\ln(C_c/C_d) - \ln(p_c/p_d)] \qquad (2)$$

where r_a is the atomic radius of the noble gas, a, and so on.

Figures 2 and 3 compare the noble gases in the Mount Capulin lava rocks with the equilibrium lines defined by equation (2) for noble gases from the Earth's atmosphere[15] and from an atmosphere containing cosmic abundances of noble gases[14]. Values of atomic radii given by Pauling[31] were used. The figures give the noble gas ratios used by Fisher[9,21,22] and by Dymond and Hogan[20] to distinguish primordial from atmospheric gases. Since the slope which we calculated from equation (2) for the plot of log(Kr/Xe) against log(^{36}Ar/Kr) is significantly steeper than that shown by Fisher[9,21] and Phinney[18], and since differences in the slopes may lead to different conclusions about the origin of noble gases in certain samples, their value for the slope has been shown (Fig. 2). Experimental values[16] for the solubility of He, Ne, and Ar in enstatite melts, and extrapolated values[16] for the solubility of Kr and Xe, have been used to calculate the noble gas ratios in a melt which sampled gases from the atmosphere, and these ratios agree with the solid equilibration lines (Fig. 2a).
Fig. 3 A comparison of noble gas ratios in the Mount Capulin lava rocks and in other material. The solid lines were calculated from equation (2) and define the noble gas ratios in samples which have equilibrated with gases having atmospheric[15] and cosmic[14] abundances. Symbols as in Fig. 2.

All of the noble gas ratios in Fig. 2 represent terrestrial samples, except for two data points representing the Bruderheim chondrite[32] and the Murray carbonaceous chondrite[26]. The ratios of these three heavier noble gases in terrestrial samples lie on both sides of the atmospheric equilibration line, with the gases in three shale samples[13] and the coal sample[13] lying close to that expected from equilibration with atmospheric gases. Noble gases in seven basalt samples analysed by Fisher[9] are generally to the left of the atmospheric equilibration line, and noble gases in tektites[8], in samples from the Vema Fracture Zone of the Atlantic[21,22], in glassy outer portions of basalts

from mid-ocean ridge[20], and in the Mount Capulin basalts are generally to the right of the atmospheric equilibration line. One view of the data shown in Fig. 2 is that those terrestrial samples lying between the atmospheric and the cosmic equilibration lines may have sampled a mixture of atmospheric and primordial gases within the Earth[20-22].

All of the non-radiogenic noble gases, including Ne, have been included in Fig. 3. Fewer data are presented there because of the absence of Ne analyses on the coal, several shale samples, or basalts from the Vema Fracture Zone of the Atlantic. The noble gas ratios in the Mount Capulin basalts, as well as in the Bruderheim and the Murray chondrite, lie close to the ratios to be expected if equilibrium with cosmic noble gases had been obtained. All of the noble gas ratios in the terrestrial samples shown in Fig. 3, however, lie to the left of the air equilibration line, and many are shifted far to the left of the line which defines equilibration with cosmic abundances of noble gases. In view of the fact that the terrestrial samples, which lie to the left of the cosmic equilibration line in Fig. 3, lie between the atmospheric and cosmic equilibration lines in Fig. 2, it seems that the position of these noble gas ratios in Fig. 2 does not necessarily indicate equilibration of the melts with a mixture of primordial and atmospheric gases[20-22]. Rather, it seems that the low Kr/Xe ratios shown in Fig. 2 may result from the fact that the Kr/Xe ratio for the Earth is appreciably lower than the Kr/Xe ratio for the atmosphere, as has been noted earlier[13], and the high Ne/Kr ratios shown in Fig. 3 may result from the preferential leakage of Ne into igneous rocks which form near the Earth's surface and have very low amounts of indigenous noble gases.

These analyses reveal the presence of a large excess of 'parentless' ^{40}Ar, though radiogenic ^{129}Xe was not observed. The abundance pattern of gases released at the highest extraction temperatures suggests that there has been little or no exchange of atmospheric xenon with these gases. The absence of radiogenic ^{129}Xe in basalts which have trapped ^{40r}Ar from the magma implies that this is not the source of radiogenic ^{129}Xe in CO_2 gas wells.

Existence and possible roles of transcriptional barriers in T7 DNA early region as shown by electron microscopy

Jean-Luc Darlix & Mireille Horaist

Service de Biochimie (142), Département de Biologie CEN Saclay, BP 2 91190 Gif/Yvette, France

Transcription of T7 DNA in vitro by Escherichia coli RNA polymerase in the absence or presence of termination factor p has been studied extensively using electron microscopy. It is demonstrated that sequences located between the early genes behave as transient transcriptional barriers in the absence of p and are recognised both as p-dependent terminators and as RNaseIII cleavage sites.

IN the current model for selective transcription, initiation and termination of RNA transcripts are dictated by specific signals on the DNA template that are recognised and translated into biochemical events by the transcription apparatus.

Specific initiation of RNA synthesis has been studied extensively *in vitro* using a model 'transcription of T7 DNA by *E. coli* RNA polymerase' that requires no added factor other than DNA and RNA polymerase holoenzyme[1]. It has been shown that a subunit of RNA polymerase holoenzyme, the σ factor, governs the tight binding of RNA polymerase molecules[1] to three specific sites within the early promotor region of T7 DNA (ref. 2), from which region RNA chain initiation takes place very rapidly in the presence of ribonucleoside triphosphates[3-5]. Darlix *et al.*[6] found that the subsequent elongation of RNA is discontinuous, that is, during the transcription of a long DNA sequence, regions of rapid transcription alternate with regions of slow transcription. More precisely, previous investigations have clearly indicated that the discontinuities in the transcription process are caused by sequences present only in natural DNAs and probably located between genes[7], and that such sequences in the T7 DNA early region could well include p-dependent termination sites[7].

We describe here the discontinuous propagation of *E. coli* RNA polymerase on T7 DNA template, as well as the action of p on this process, as observed by electron microscopy.

Discontinuous transcription of T7 DNA

Discontinuous transcription of DNA is best observed when the RNA chain growth rate is reduced; this is obtained by decreasing the concentration of one nucleotide[6]. As previously shown[7], transcription of T7 DNA with or without p is clearly discontinuous in conditions in which GTP concentration is lowered to 1.5×10^{-5} M. Successive plateaux occur during the kinetics of total RNA synthesis in the presence or absence of p. We have located the growing RNA on the physical map of T7 DNA at times corresponding to the plateaux (Fig. 1).

The DNA–RNA polymerase–RNA transcription complexes have been studied in the electron microscope by dark-field observation of specimens prepared by adhesion on positively charged carbon films[8]. In the present conditions and in the absence of p, growing RNA chains ap-

pear as clustered bushes on the DNA (Fig. 2). If transcription is stopped after 4, 11 and 25 min, that is, when RNA synthesis is particularly low (plateaus, Fig. 1), most active enzymes are found at or near the end of gene 0.3— the first one[6]—(Fig. 3a), the end of genes 0.3 and 0.7 (Fig. 3b), and the end of genes 0.7, 1 and 1.1 (Fig. 3c), respectively. Previous results of the RNA chain length analysis of the corresponding transcription products agree with the present findings[7]. In fact, the mRNA of gene 0.3, of genes 0.3 and 0.7, and of genes 0.3, 0.7 and eventually 1 and 1.1
Fig. 1 Discontinuous transcription of T7 DNA *in vitro*. T7 DNA, *E. coli* RNA polymerase and factor p were prepared as described previously[7]. The reaction mixture contained 52 µg T7 ^{3}H–DNA (4,000 c.p.m. µg^{-1}), 10 µg RNA polymerase (50–70% active based on the specific activity reported by Burgess[11]), 7 µg p when added (○), 0.1 mM ATP, CTP, α-^{32}P-UTP (300 mCi mmol^{-1}), 0.015 mM GTP and salt conditions as described previously[7], final volume 2.5 ml. Where indicated, 75-µl aliquots were withdrawn and RNA recovered by acid precipitation. Insert, general aspect of the kinetics of RNA synthesis with T7 DNA template at limiting GTP concentration. In these conditions, the relative molar ratios of RNA polymerase to p and T7 DNA are 6:14:1 assuming respective molecular weights of 490,000, 250,000 and 25×10^6. ●, RNA made in absence of p; ○, in presence of p.
Fig. 2 Discontinuous transcription observed using electron microscopy. Conditions of transcription are those in Fig. 1. The samples were diluted to a concentration of 0.1 to 0.5 µg ml^{-1} T7 DNA with an ice-cold buffer (that of transcription) and specimens prepared as described previously[8]. Observations were made with a Siemens Elmiskop 101 electron microscope. The dark field was obtained by the tilted beam method and a thin-film objective aperture of 20 µm was used. Micrographs were recorded on 65×90 mm Kodak films at magnification ranging from 13,000–40,000. *a*, After 4 min transcription, small RNA bushes are visible. Magnification: ×80,000. E, DNA end; R, RNA bushes. *b*, After 11 min transcription, two DNA molecules are spread in the field and several RNA bushes are clustered at the end of gene 0.7. Magnification: ×65,550. *c*, After 4 min transcription in conditions which all four nucleotides were present at 0.1 mM. One entire DNA molecule is spread in the field and most RNA bushes visible are at the end genes. Small RNA bushes may be seen near one DNA end. Magnification: ×51,300.

were synthesised after, respectively, 4, 10 and 20 min of transcription at low GTP concentration. Consequently, sequences located between genes in the T7 DNA early region behave as transient transcriptional barriers. In addition, transcribing RNA polymerases also stop in the middle of gene 1, indicating the presence of a transcriptional barrier in this region[7]. In the present conditions total RNA synthesis ceases after 50 min and the major product is the polycistronic mRNA of T7 DNA early region as usual[7] (Fig. 1, insert).

On the basis of the above data we can estimate the relative times devoted to high and low rates of transcription and RNA chain growth rate. During 25 min of transcription, efficient RNA synthesis occurred during approximately 8 min (Fig. 1); thus a third of the time is devoted to efficient synthesis. These 8 min should be considered as a maximum, for the first 2 min of RNA synthesis are devoted to initiation (result not shown). As DNA sequences of 2,500 to 6,500 nucleotides have been transcribed within these 6–8 min of efficient synthesis (Fig. 3c), RNA chain growth rate varies from 5 to 18 nucleotides s^{-1}. Furthermore, in 3 min (third to fourth plateau, Fig. 1) RNA polymerase molecules can transcribe a sequence 3,600 nucleotides long, that of genes 1 and 1.1 (Fig. 3b and c), then at a chain growth rate of 20 nucleotides s^{-1}. Transcription of gene 0.7 proceeds at the same speed (second to third plateau, only a small fraction of enzymes have reached the end of gene 0.7 at 7 min; result not shown). Finally, assuming that all enzymes transcribe the genes at 20 nucleotides s^{-1}, the most efficient have read four genes (0.3 to 1.1; 5.5 min required) after 25 min synthesis, whereas

the less efficient enzymes have read only two genes (0.3 and 0.7; 2 min required).

On the other hand, transcription of the sequences located at the end and/or beginning of the early genes seems to proceed slowly and last a long time. If we estimate that the length of each transcriptional barrier does not exceed 190–285 nucleotides (0.50–0.75 T7 DNA map unit, Fig. 3 and ref. 10), the corresponding RNA chain growth rate should be about 10–60 nucleotides min^{-1}.

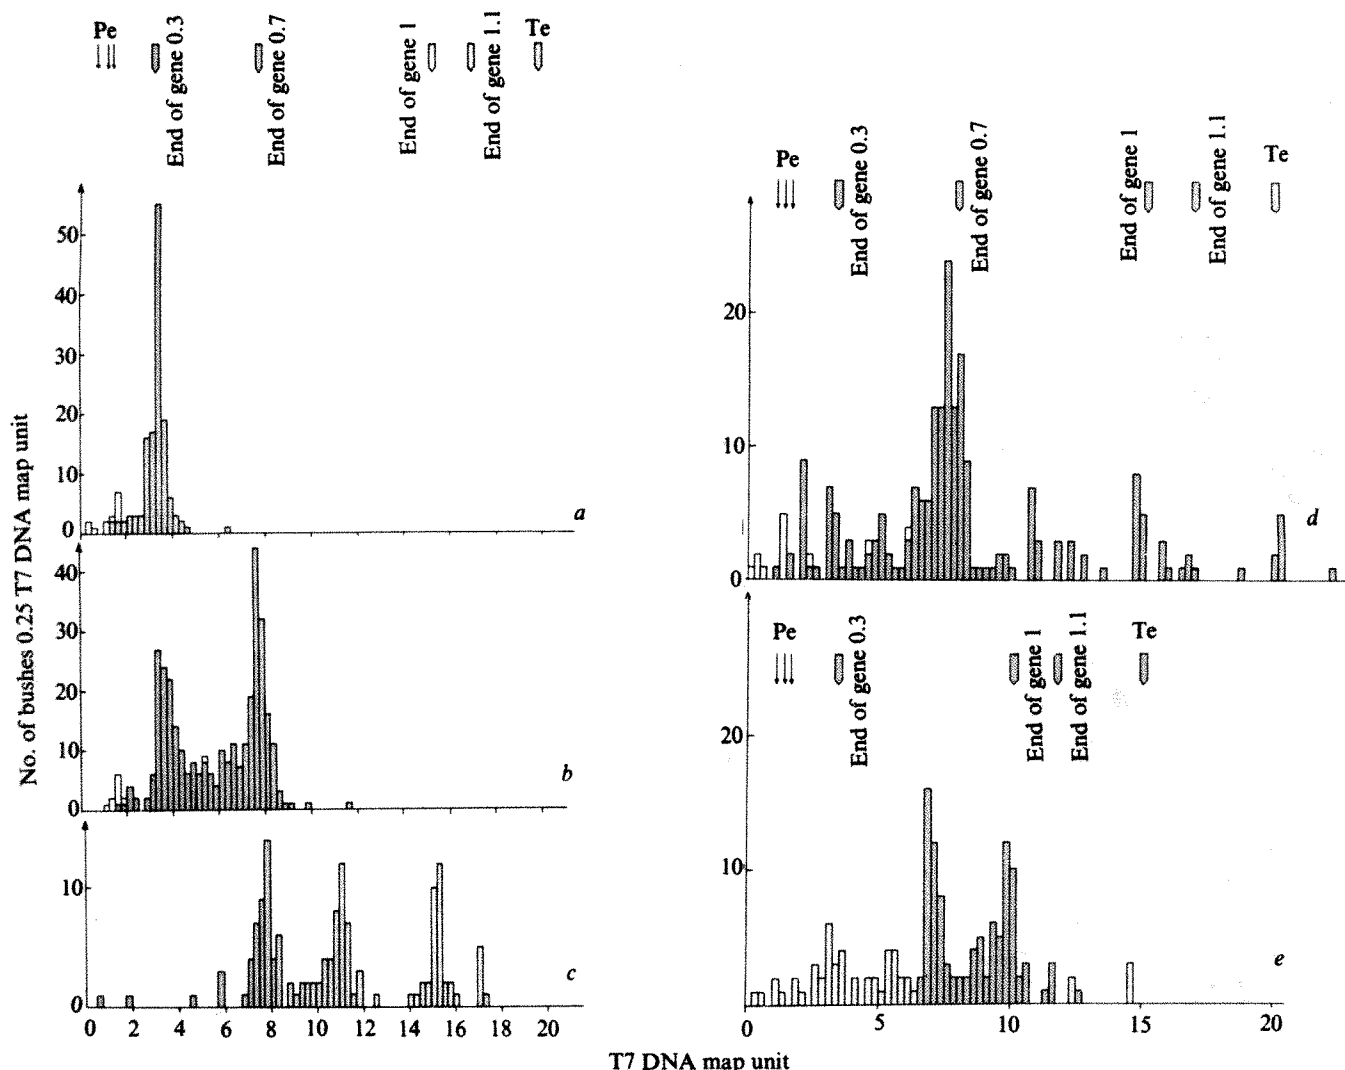
Thus all these calculations show that, at limiting GTP concentration, efficient transcription may well correspond to the rapid and brief synthesis of specific RNAs and low rate of transcription to the slow growth of short and particular RNA sequences[4,7,10]. A similar transcription pattern can be drawn from results of experiments in which the limiting nucleotide was CTP or UTP instead of GTP (results not shown). If the present conclusions are independent of the low concentration used for one nucleotide, a large fraction of the polymerases should also be found between genes after a given period of synthesis carried out at 50–100 nucleotides s^{-1}, that is, when the concentration of each nucleotide is 0.1 mM (ref. 6). In fact, after 4 min transcription with T7 DNA template, growing RNA transcripts are clustered near the end of genes, mostly at the end of gene 0.7 (Fig. 3d). Chain length analysis of the transcription product agree with the present findings, as most RNA are 2,300–3,000 nucleotides long corresponding to the transcription of genes 0.3 and 0.7 (results not shown). At a chain growth rate of 50–100 nucleotides s^{-1} (ref. 6), transcription of genes 0.3 and 0.7 should have required 30–60 s of the 4-min synthesis; thus the relative time de-


Fig. 3 Histograms of the positions of the transcription complexes. Experiments were carried out as described in Figs 1 and 2. Interesting features of the micrographs taken were redrawn on paper at ×10 magnification using an Automega enlarger. Length measurements were made on these drawings with a map ruler. One T7 DNA map unit corresponds to 380 base pairs. Mapping was according to Simon and Studier[9]. *a*, After 4 min transcription, 146 RNA bushes were on 62 DNA molecules. 58 free DNA ends observed. *b*, After 11 min transcription, 328 RNA bushes were on 135 DNA molecules. 100 free DNA ends. *c*, After 25 min transcription, 140 RNA bushes were on 53 DNA molecules. 50 free DNA ends. *d*, After 4 min transcription in conditions in which all four nucleotides were at 0.1 mM, 230 RNA bushes were on 79 DNA molecules. 70 free DNA ends. *e*, As in *d* but the template used was T7 C18 DNA, 153 RNA bushes were on 50 DNA molecules. 40 free DNA ends. Open areas, complexes in which RNA is hardly visible; stippled areas, complexes in which RNA is clearly visible.

voted to rapid transcription is roughly the same whether GTP concentration is limiting or not, and equal to 10–25% of the total transcription time.

With T7 C18 DNA template (in which regions of gene 0.7 and between 0.7 and 1 are deleted[8]) most transcribing RNA polymerases are not located in the same regions of the T7 DNA physical map, but again are still close to the end of genes and in the middle of gene 1 (Fig. 3*e*). After 15 min transcription and in conditions in which the RNA polymerase is in large excess, the growing RNA transcripts are mostly at the end of genes[12].

Transcriptional barriers associated with termination of RNA synthesis

We have shown above that regions located between genes behave as transient transcriptional barriers. In the absence of *ρ*, spontaneous termination of RNA synthesis seldom occurs at these sites[13] and they are transcribed. The double-stranded RNA that results is further digested by RNaseIII during the processing of the mRNA of the T7 DNA early region[4,10,14,15].

Addition of factor *ρ* to the transcription apparatus does not modify the binding of RNA polymerase to the DNA (ref. 2). As shown by electron microscopy, at respective molar ratios of RNA polymerase to *ρ* and T7 DNA of 6 : 14 : 1, three to four enzymes bind to the three to four sites located in the early promotor region at 1.1, 1.41, 1.65 and 0.5 units of T7 DNA physical map[2] (Figs 4 and 5). RNA synthesis very probably starts from these sites[7] and proceeds discontinuously in the presence of *ρ* (Fig. 1). In conditions of limiting GTP concentration, inhibition of transcription caused by *ρ* begins after 4–5 min; at that time most active enzymes have transcribed gene 0.3 and are between genes 0.3 and 0.7, where factor *ρ* specifically terminates transcription for the first time[7]. After 11 min of synthesis, termination of transcription intervenes once more between genes 0.3 and 0.7 and between genes 0.7 and 1. Transcription with *ρ* is completed after 20 min (Fig. 1, insert) and the major products are monocistronic mRNA of gene 0.3 (plus a part of the early promotor region) and of

gene 0.7 in a molar ratio 4 : 1 (Figs 4 and 5 of ref. 7).

The action of ρ may be seen clearly in Figs 4b and 6a, which show the localisation of RNAs still attached to the DNA after 11 min of transcription. The number of RNA bushes per T7 DNA molecule is two- to threefold less with termination factor ρ than without; RNA bushes are no longer clustered (Fig. 4b). An unusual number of RNA polymerases that have just initiated transcription are present in the regions of the early promotor and end of genes 0.3 and 0.7 (Fig. 6a). Remaining RNAs are not at the end of genes 0.3 and 0.7, but located between early promotor and the end of gene 0.7 and primarily within gene 0.3. Transcription complexes are also present between genes 0.3 and 0.7 indicating that ρ is not completely efficient and/ or part of the sequences at the end of genes are transcribed in the presence of ρ. Similar conclusions can be drawn from the distribution pattern of the RNA bushes after 4 min transcription with ρ in the presence of saturating concentration of the four nucleotides (Fig. 6c, for control see Fig. 3d).

Our findings establish certain aspects of the proposed mechanism for T7 DNA transcription with ρ. Transcription starts within the early promotor region, very probably at the three binding sites; data presented in Fig. 6 support the idea that reinitiation of transcription at the early promotor and at the beginning of genes 0.7 and 1 (ref. 16) follows the termination of transcription maximised by ρ at the end of genes 0.3 and 0.7 (refs 7, 13, 16). As there is no preferential degradation of one or more early T7 mRNA *in vivo*, our data clearly indicate a possible way in which transcription of the T7 early genes are modulated *in vivo*[17-19]. RNA transcripts made in the presence of ρ

Fig. 5 Position of the RNA polymerase binding sites in T7 DNA early promotor region in presence of ρ. Specimens were prepared and analysed as described in Figs 3 and 4. Histogram of the positions of 114 RNA polymerase molecules on 38 T7 DNA molecules. One T7 DNA unit corresponds to 380 base pairs.

are processed by RNaseIII to give monocistronic mRNA of T7 DNA early region identical to those found *in vivo* and in similar relative ratios[7].

Finally, the action of ρ between genes is well shown in Fig. 6b. After transcription without ρ and at limiting GTP concentration, ρ is added (plateau, Fig. 1). One minute later the synthesis is stopped and the distribution pattern of the growing RNA chains determined. Almost all RNA transcripts clustered at the end of genes 0.3 and 0.7 have disappeared (70% total RNA chains), whereas those within gene 0.3 remain (for control, see Fig. 3b).

Conclusions

It now seems possible to draw the following picture for the *in vitro* synthesis of a polycistronic mRNA such as that of the T7 DNA early region. Once RNA chain initiation is completed, intense bursts of transcription of long DNA sequences, the genes, alternate with the slow synthesis of short and particular RNA sequences which takes a long time to complete.

On the basis of our experiments and on those of others (for review see ref. 1), we may well understand the mechanism of *in vitro* ρ-dependent termination of transcription. ρ Termination is directly related to the decrease in RNA chain growth rate at the end of genes and in the middle of gene 1. Furthermore, efficiency of ρ terminations is also related to the time necessary for RNA polymerase to read through a transcriptional barrier. When the mean chain growth rate is decreased by limiting concentration of one nucleotide, transcription beyond gene 0.7 does not occur, or at least is extremely low[7]. In addition, all attempts made to demonstrate the presence of ρ-specific binding sites on T7 DNA, as on fd DNA[20], were unsuccessful. Intervention of ρ during transcription may well seem to be a probable and transient interaction between this factor and slowly transcribing RNA polymerases, the conformation of which has been modified by a transcriptional barrier.

Such T7 DNA sequences, which include ρ-active sites, also coincide with the corresponding RNaseIII cleavage sites, of the RNA transcript[4,7,14]. Data now available show that of these DNA sequences some should be $(dA)_n$: $(dT)_n$-rich[10,21] and other $(dC)_n$: $(dG)_n$-rich[10], and expected to be

Fig. 6 Positions of the transcription complexes in presence of ρ. Experiments were carried out as in Figs 1–3. *a*, ρ added together with RNA polymerase, and transcription was stopped after 11 min. 120 RNA bushes were on 96 DNA molecules, 100 free DNA ends observed. *b*, ρ was added after 10 min transcription, itself stopped 1 min later. 121 RNA bushes were on 64 DNA molecules. 110 free DNA ends. *c*, ρ was added together with RNA polymerase, and transcription was carried out in conditions in which all four nucleotides were at 0.1 mM. 140 RNA bushes were on 100 DNA molecules. 100 free DNA ends. Open areas, complexes in which RNA is hardly visible; stippled areas, complexes in which RNA is clearly visible.

preceded by a specific sequence –G–C–C–U–U–U–A–U– – and followed by –G–A–U– (ref. 22).

More generally, similar transcriptional barriers probably exist in all natural DNA as indicated by the heterogeneous distribution of the RNA made in the course of transcription with T4, φ80, λ, *E. coli* and calf thymus DNA templates[7], and these barriers exert a control on transcription in the presence or absence of an additional factor[1] We have shown termination of T7 DNA transcription under the control of ρ; this process has also been described with various natural DNAs but not with artificial templates[1] and thus seems to be a general phenomenon requiring specific DNA sites and ρ. Another termination event occurs at the end of the early region of T7 DNA and is ρ independent[23]; the barrier located at 20% of the T7 DNA physical map, however, does not stop all transcriptions and its efficiency decreases with increasing concentration of salt[16]. Such transcriptional barriers are not rare and exist within the late region of T7 DNA[23], and also within λ and *E. coli* genomes[24,25].

Finally, transcriptional barriers can be located very close to the promotor region of a bacterial operon, and could thus be important in the control of transcription of one or more structural genes. In the course of transcription of the tryptophan operon, RNA polymerase is frequently reiected at a specific site ahead of the first structural gene, but a protein factor was found to antagonise the abortive synthesis of tryptophan mRNA[26].

Hard X-ray observations near Ariel 1118 – 61

OBSERVATIONS made by Ariel V in the region of Cen X-3 have revealed a new transient X-ray source with a periodicity of 6.75 min (refs 1 and 2). Tentative identifications are: with a Mira-type variable star by Fabian *et al.*[3], who suggest the 6.75 min periodicity is associated with the rotation period of a compact companion; and with a heavily reddened, variable

ultraviolet star[4]. As well as the proportional counter observations during the period 1974 December 17 to 1975 January 31, the Imperial College crystal scintillator, sensitive to the photon energy range 26 keV to 1.2 MeV, viewed the same region of the sky. This detector has a sensitive area of 8 cm², an opening angle of 8° FWHM defined by an active collimator and is offset from the spacecraft spin axis by an angle of 3°. A source a few degrees from the direction of the spin axis can be detected

by determining the modulation in the counting rate seen in four equal angle spin sectors with a time resolution of 512 s. A single channel (50–190 keV) mode with a 48 s time resolution was also used. Since a spurious modulation is induced in the apparatus by cosmic rays, two pointing direction offsets on opposing sides of the source have to be used, and the X-ray contribution is obtained by a subtraction technique.

Scheduled observations of Cen X-3 coincided with an extended low from 1974 December 17 to 1975 January 10 and no detectable signal was seen above statistical noise. The offsets were, however, equally good for putting upper limits on the hard flux of A1118−61 (Table 1).

Table 1 Upper limits on A1118−61 flux

Period	2σ upper limits (photons cm^{-2} s^{-1} keV^{-1}) 40 keV	80 keV	180 keV
1974 December 19–22	3.4×10^{-4}	1.8×10^{-4}	4.0×10^{-5}
1975 January 8–11	5.4×10^{-4}	1.7×10^{-4}	7.8×10^{-5}

To compare these results with those reported at lower energies, we note that Ives *et al.*[2] find the spectral shape varies little during their observations using proportional counters. We can therefore scale the proportional counter spectrum given by these workers, according to the light curves of references 1 and 2 to obtain the low energy spectrum corresponding to our periods of observations. Figure 1 shows the result of this procedure with the proportional counter points reduced by a factor of 2.3 to correspond to the epoch 1974 December 19–22. Our 2σ scintillator upper limits are plotted at the logarithmic

Fig. 1 Four independent, hard X-ray upper limits plotted at 2σ for the spectrum of A1118−61 together with low energy X-ray data normalised to the same epoch (1974 December 19–22). Three theoretical fits to the data are also shown: *a*, 3 keV black body spectrum; *b*, 7 keV black body spectrum modified by electron scattering; *c*, 20 keV thermal bremsstrahlung spectrum +, proportional counter data; ○, offset mode; ☐, search for 6.75 min period.
mean energy of the channels and are virtually independent of the assumed spectral slope within the channel.

A further independent upper limit for the 6.7506 ± 0.006 min periodicity (J. Bell Burnell, personal communication) has been obtained using observations with the 48 s time resolution mode made in the period 1975 January 19–27. These data, which are less sensitive to the cosmic ray induced background, were folded with the quoted period. A 2σ upper limit for the depth of modulation of 3×10^{-5} photons cm^{-2} s^{-1} keV^{-1} was obtained. This value, which has been normalised to a photon energy of 100 keV, is almost independent of the assumed spectral shape within the energy window for a range of likely cosmic spectra. Assuming there is essentially 100% modulation as indicated in reference 2, the above limit must be approximately halved for comparison with the time averaged data. But since the intensity may be a factor of two lower for this observation than for the standard epoch (that is, 1974 December 19–22) we plot 3×10^{-5} photons cm^{-2} s^{-1} keV^{-1} as the corrected 2σ upper limit in Fig. 1.

In discussing the physical processes for the emission implied by the combined spectral measurements, it is clear that any power law spectrum fitted above 10 keV must be steeper than E^{-3}, although the published low energy data enabled even an E^{-1} fit. Thus there is no immediate reason to consider a synchrotron source. Instead, consider accretion on to a compact stellar object in a binary system. Indeed we note that the rapid spectral cutoff below 4 keV suggests strong local gas absorption[2]. The dominant mechanism for emission of X rays from the gas clouds accreting on to the compact object could be either (a) a black body radiation where photon scattering by electrons is unimportant, or (b) a modified black body radiation at a higher temperature with a significant skin depth so that photons must random walk. We may further modify (b) by adding a high temperature bremsstrahlung tail (free-free emission) due to inner regions of the accretion cloud shining through at harder X-ray energies. Our best fit to hypothesis (a) using a photon spectrum

$$(dI/dE)_{BB} \propto E^2/(\exp(E/kt)-1)$$

yields $kT = 3 \pm 1$ keV and this is plotted in Fig. 1 as curve *a*. Fitting a modified black body spectrum (curve *b*) to the proportional counter data using

$$(dI/dE)_M \propto (dI/dE)_{BB}[gE^{-3}(1-\exp(-E/kT))]^{1/2}$$

with the Gaunt factor $g \propto E^{-0.4}$ gives $kT = 7$ keV ± 1 keV. But plotting this spectrum in Fig. 1 results in a curve which is a poor fit to the lowest in energy of the scintillator counter 2σ upper limits and does not satisfy the proportional counter data so well. A thermal bremsstrahlung spectrum (*c*) with $(dI/dE)_{TB} \propto E^{-1.4} \exp(-E/kT)$ and $kT \sim 20$ keV is a plausible fit to the higher energy proportional counter data but is similarly inconsistent with the hard X-ray data. We conclude that the addition of scintillator X-ray data to the A1118−61 observations suggests that if a dominant, single source mechanism is sought, black body radiation from a low skin depth gas is the most likely.

Radio emission from Cyg X-3

THE most recent radio outburst of Cyg X-3 reported[1,2] occurred in May, 1974. Following the announcement by Ryle[1] of high activity we observed part of this outburst at 4.8 GHz with the 100-m telescope of the MPIfR at Effelsberg from May 22 to May 31, during a general survey of the Cygnus X region. The observed flux densities are summarised in Fig. 1 and have typical errors of 3% or less; the general behaviour of the sources is also sketched in
Fig. 1 Light curve of Cyg X-3 at 4.8 GHz (filled circles). The dashed lines sketch the data from Seaquist *et al.*[2].

for the data given by Seaquist *et al.*[2]. The observations were obtained as a flux density ratio with respect to NGC7027 from direct adjacent crosscuts, assuming a value of 5.8 Jy for NGC7027 (from refs 3 and 4). As our data did not contain very extended polarisation measurements and as they are consistent with the interpolated polarisation properties given in ref. 2, all points were brought to the mean flux density level using a polarisation angle of 70° and a linear polarisation of 4.7%.

Three important results emerge from our study. First, the source also shows the linear decay of long time averaging over the missing time interval of ref. 2. (For a discussion of related problems see ref. 5.) Second, the periodicity indicated in the detailed flux density behaviour is also visible in our data. Moreover we have the impression that this periodicity becomes less pronounced when progressing from May 22 to May 31. Third, we emphasise that it may be dangerous to infer a 'linear' spectrum from only two points. In Fig. 2 several spectra are shown constructed from the data of

ref. 2 and our observations. There is a strong indication that the assumption of optically thin properties may not be valid even during the decay of this outburst. This does not seem to be a systematic calibration effect between the two sets of observations.

Forcing our data down to an interpolated value on the 'linear' spectra would require us to assume for NGC7027 at 4.8 GHz a flux density value of 5.3 Jy or less which seems completely out of the question according to the spectrum given by Higgs[3] and Ross and Seaquist[4]. From a few flux density ratio measurements NGC7027/3C48 we derived a value of 5.4 ± 0.3 Jy for 3C48 which is compatible with an interpolated value used in ref. 2. Thus, during the time May 22 to May 31 the spectra may be interpreted as showing the effects of optical depth (see ref. 6). A possible explanation of this behaviour may be that the sum of the recent outbursts has accumulated enough thermal plasma on the outskirts of the source for absorption now to occur even at frequencies up to several GHz.

The activity of Cyg X-3 has been quite high during the past few years and it is almost possible to say that the source underwent an outburst once every month. The source was visible for about a couple of weeks at an appreciable flux density level during each flare. So the question of past activities of the source may be important for all explanations of the nature of the source. One of us (H.J.W.) has obtained many observations of the area during regular surveys of the

Table 1 Older data for Cyg X-3

Date	Frequency (GHz)	Upper limit (Jy)	Telescope
1964

Cygnus X region[7,8]; activity at the present level had a high chance of being discovered. But the data would have been regarded as showing a spurious source. So we re-examined the old records. The dates of observations and the derived upper limits (3σ) are given in Table 1. Especially during July 1964 and January 1965, outbursts such as, for example, those occurring in September 1972 and in May 1974 would easily have been seen. We are tempted to conclude that ten years ago the source was not so active as today.

The 'spectra' of the solar cycle and of data for Atlantic tropical cyclones

TROPICAL cyclones (including hurricanes) are significant climatic features which affect the South and East USA as well as areas of the western Atlantic, the Caribbean, and the Gulf of Mexico. Since they are considered to be a mechanism which limits the build-up of heat and energy in tropical regions[1], cyclones are necessarily related to large scale circulation patterns which may be global in extent. Thus, if a relationship is to be found between solar activity and large scale meteorological phenomena, we may expect that it will evidence itself in analyses of data on cyclone occurrence and the length of the cyclone season. Here we report results of such a study, and provide evidence which is consistent with the hypothesis that a relationship exists between the solar cycle and the occurrence of Atlantic tropical cyclones.

The data sets analysed[2,3] relate to tropical cyclones which originated in the Atlantic region during each month from 1871 to 1973 (see ref. 2 for a discussion of the sources and quality of the cyclone data). Both the number of cyclones which occurred in each year, and the length of the annual cyclone season in months (counted as the number of months from the month of the first cyclone to the month of the last cyclone, inclusive), were extracted from the data and were smoothed with a 7-yr running mean filter (Fig. 1a, b). Also shown in Fig. 1 are the 12-month running mean sunspot numbers[4,5] (Fig. 1c). It was necessary to smooth the cyclone data to ensure that scatter in the data did not cause the maximum entropy spectral analysis (MESA) technique (based on an autoregressive description of the data by Burg (unpublished); see also ref. 6) to fail to give acceptable spectral estimates[7].

MESA spectra for the smoothed number of Atlantic tropical cyclones and the smoothed length of the cyclone season are shown in Fig. 2a and b. For comparison, the MESA spectrum for the 12-month running mean sunspot numbers[8] (1750-1963) is given in Fig. 2c. Use of a longer time period in the analysis of the sunspot data is based on the assumption that all of the time series analysed here are stationary. Though spectral components determined using the MESA technique may be shifted somewhat in frequency[7], similarities in the spectra are evident. Note that long-period components in the spectra for the cyclone data
Fig. 1 *a*, 7-yr running mean number of Atlantic tropical cyclones; *b*, 7-yr running mean length of Atlantic tropical cyclone season; *c*, 12-month running mean sunspot numbers.

at 133 yr (Fig. 2a) and 154 yr (Fig. 2b) may represent ill-defined estimates for the 96 yr component found in the spectrum for the sunspot data. That these estimates are shifted to longer periods may result from the initial phase of the long period component in the window analysed or from the limited length of data available for analysis[7]. It is also possible that the data from 1871 to 1905 underestimate the number of cyclones which occurred each year as well as the annual lengths of the cyclone seasons, thereby introducing a long period bias into the data (after 1905, the use of radio aboard ships at sea greatly increased the quantity and quality of weather data acquired).

With respect to the 11-yr periodicities in tropical cyclone occurrence and length of season, it is interesting that some data for other meteorological phenomena exhibit this same periodicity. For example, Currie[9] observed a 10.6-yr periodicity in the spectra of surface air temperature data from North America, and concluded that solar activity has measurably affected this climatic element.

Although prominent spectral components at periods of 15 and 22 yr are found in the MESA spectra for the data on the length of the cyclone season, and appear only weakly in the sunspot spectrum, similarities in the MESA spectra
Fig. 2 Maximum entropy spectra for data shown in Fig. 1. *a*, Number of tropical cyclones; *b*, length of tropical cyclone season; *c*, sunspot numbers (spectra computed from data in the interval 1750–1963).

for the smoothed number of North Atlantic cyclones, the smoothed length of the cyclone season, and the 12-month running mean sunspot numbers suggest that a relationship exists between the solar cycle and Atlantic tropical cyclones. Whether the 22-yr periodicity found in the tropical cyclone data has its origin in the reversal of the magnetic fields associated with sunspots (the so-called "Hale double sunspot cycle") is speculative. The possibility that a long period resonance exists in the Earth's response to solar radiation must also be considered.

We offer no explanation as to how variations in the solar cycle influence the tropical cyclone phenomenon, and more generally, the climate.

We thank Dr R. Blandford and the referees for comments.

Odd and even numbered year summer temperature pulse in central England

Meteorologists and amateur weather observers with long memories have noted for some time that there seemed to be a preference for the hottest summers to occur during odd numbered years and the coolest during even numbered years during this century in south-eastern England. Many studies made during the past decade have supported the validity of such recollections for a much wider area. For example, Sutton[1] and Murray[2] have identified the existence of a biennial oscillation of the atmosphere and discussed its effects on the tropospheric circulation in both tropical and temperate latitudes. Davis[3] has found a high statistical significance in temperature differences between odd and even numbered years for an extensive area of western Europe.

The publication[4] of temperature observations for central England brings this long series up to date. The series, starting with 1721, has now been examined again to test whether the even–odd year cycle is peculiar to the summers of the present century, or whether it is indeed a long term feature of our climate. Data from years before 1721 have been excluded as they are less reliable. We have used the month of July; as the July temperature in England is highly correlated with sunshine and low rainfall it can be used as a good index of summer weather.

To remove the influence of longer period oscillations in the data, the anomalies in temperature for each year were obtained by using averages taken over decades. We have defined a tercile distribution of anomalies greater than + 0.4 °C, within ± 0.4 °C inclusive and less than − 0.4 °C. The distribution within these classes for even and odd years is shown in Table 1.

Table 1 Distribution of temperature anomalies in July (1721–1970)

	$A > + 0.4\,°C$	$B \pm 0.4\,°C$	$C < - 0.4\,°C$	Total
Even years	30	47	48	125
Odd years	51	26	48	125

The χ^2 test shows that the distributions are significantly different to the 1% level. The differences show that in 21 even Julys there is a shift from above average to average compared with the odd Julys: the probability of an above average July in an odd year is 0.41 compared with 0.24 in an even year. The probability of a below average July is 0.38 for both odd and even years.

The period from 1911 to 1970 was examined separately. The distributions are shown in Table 2. The probability of having an

Table 2 Distribution of temperature anomalies in July (1911–1970)

	$A > + 0.4\,°C$	$B \pm 0.4\,°C$	$C < - 0.4\,°C$
Even years	5	11	14
Odd years	14	9	7

above average July in an odd year has increased to 0.47 as against 0.17 for an even year. Likewise, the probability of a cool July in an even year has increased to 0.47.

The results show that in the whole period from 1721 to 1970 a highly significant biennial pulse is occurring in the July temperatures. The main characteristic of the pulse during the

past 60 yr is the occurrence of warm Julys in odd years and cool Julys in even years, though taken over the whole 250-yr period this characteristic is not so well marked.

Brine at the bottom of the Great Bitter Lake as a result of closing the Suez Canal

DURING the process of clearing the Suez Canal and the Bitter Lakes from bombs and mines resulting from the 1967 and 1973 wars, an abnormal phenomenon was observed. Divers reported that diving was rather difficult through a layer extending about two metres above the bottom in the eastern part of the Great Bitter Lake (GBL). When this layer was reached through diving, any diver was forced to turn upwards. Moreover, sounding of depths by the use of sonic waves gave values which were less by about 2 m than when measured by weight and line.

A preliminary investigation of salinity was made on June 20, 1974, in the GBL. This showed that the salinity near the bottom was exceptionally great in many locations, especially in the eastern area of the lake. One of these locations was selected for detailed study. It was 16.5 m deep and located at a distance about 4 km east of the navigation channel. Water samples were collected at surface, 6, 12, 14 and 16 m depths, and temperatures at every depth were measured. Hydrogen sulphide was smelt distinctly in the samples collected at and below 14 m depth where several rotten fish were found. Bottom samples were sludgy and had a black colour.

Salinity was estimated by two different and independent methods after diluting the water samples with distilled water: determination of chlorinity by the Knudsen titration method[1], in which chlorinity was converted to salinity using an empirical equation suggested by Morcos and Riley[2] for the Suez Canal region, and measurement of conductivity ratio. The two methods gave very close results.

Salinity and temperature values of the water column are given in Table 1; they show that, with increasing depth, the temperature variation is within the normal range while the increase of salinity is very rapid. A layer of brine (salinity more than 300‰) about 2 m thick exists above the bottom. This exceptionally high salinity had never been reported before.

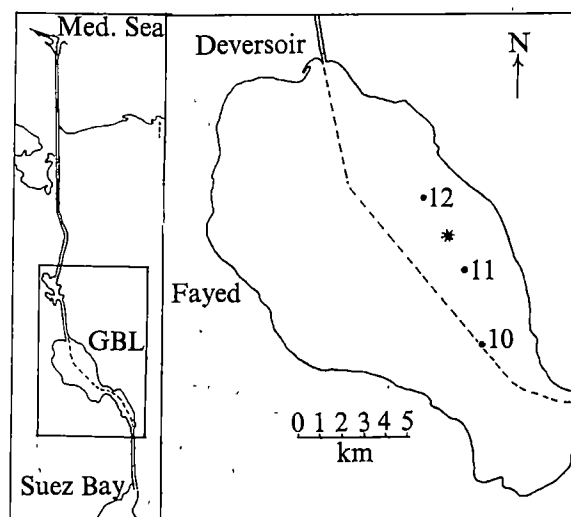
The GBL was a dry basin before it was filled by water from the Mediterranean and Red Seas in November 1869. Its bottom is formed of multilayers of salt deposits separated by films of sand and gypsum. Early investigations[3] of the salinity of the Suez Canal and its lakes showed that even during the operation of filling the GBL with sea water, the highest salinity recorded was 168.6‰ (by evaporation) when water from the Mediterranean was covering the salt bed by only 1.4 m. Evidence based on observation[4-6] of salinity in 1924–25 and 1933–34, suggests that the southern part of the canal possessed higher salinity than the GBL itself. Observations during 1954 and 1955 indicate[7] that the maximum salinity in the Suez Canal


Fig. 1 Map of the Great Bitter Lake showing the locations of stations 10, 11 and 12 occupied by El-Sharkawy[8] in April 1967 and the position (*) where the samples were collected in June 1974.

region (48.4‰) was reached in late summer in the southern canal but not over the salt bed as might be expected. El-Sharkawy[8] carried out observations of salinity in the Bitter Lakes for one year (April 1966–April 1967) and the salinity in GBL did not exceed 49‰. His last cruise (April 1967) is of great interest since it was made only two months before the closing of the Suez Canal that June. The salinity–depth profile of the three stations 10, 11, 12, which were occupied in the eastern part of the GBL (Fig. 1) is reproduced in Table 2. His deepest samples were obtained at only 12 m depth, but the salinity was increasing gently with depth and did not show any indication of an abrupt increase. By contrast, my results (Table 1) show unusually high salinity at 6 m and approach saturation at 14 m. Comparison between Tables 1 and 2 shows that my surface salinity is even higher than that obtained at 12 m on the 1967 cruise. This clearly indicates that a rather abnormal phenomenon occurred in the GBL during the period of closure of the Suez Canal.

In normal conditions the salinity of the GBL is influenced by the time of residence of water over the bottom salt deposits, the exchange of water with the southern and northern parts of the canal, and evaporation and meteorological conditions in the region. But in the special situation after the Suez Canal was closed, the first two factors were the principal causes of the exceptionally high salinity of the GBL and the formation of a brine layer near its bottom. The rate of salinity increase is directly proportional to the time of residence of water over the salt bed and inversely proportional to the rate of water flow through the Suez Canal. This was confirmed by observations[7] which show that during June–July, when the northward flow in Suez Canal becomes very slow and thus the time of residence becomes relatively longer, the salinity of the GBL reaches its maximum value of the year.

Table 1 Variation of salinity and temperature with depth at a station in the GBL (Fig. 1) occupied on June 20, 1974

Depth (m)	Salinity (‰)	Temperature (°C)
0	48.50	30.32
6	63.60	28.41
12	151.29	26.64
14	311.17	25.90
16	314.93	25.63

Table 2 Salinity–depth profile at stations 10, 11 and 12 in the GBL observed on April 5, 1967 (ref. 8)

Depth (m)	Salinity °/oo		
	10	11	12
0	43.23	43.41	43.63
3	43.48	43.75	43.93
6	43.88	43.93	44.02
9	43.97	44.04	—
12	44.35	—	—

After June 1967 the Suez Canal was closed to navigation and many obstacles and wrecks were blocking the waterway. Moreover, during the period from October 1973 to June 1974 the Canal was completely blocked by an earth dam at Deversoir where the Canal enters the northern part of the GBL. So the normal exchange of water between the Red and Mediterranean Seas through the Suez Canal was very much reduced and eventually stopped. This exchange was the chief cause for the gradual decrease of the salinity of the GBL from 168.8‰, during its filling process, to an average of 46‰ in April 1967. As the water passes over the salt bed, a considerable quantity of salt goes into solution and is eventually carried away by the water flow to the adjacent seas. In the new situation the GBL was almost isolated and its water became stationary over the salt bed allowing the salt dissolution to continue for a time long enough to bring the bottom water very close to its saturation point. The strong stratification and the great stability of the water column observed in June 1974 (Table 1) overcame the effects of wind stirring and evaporation.

The dense water (density about $1.2\,\mathrm{g\,ml^{-1}}$) near the bottom of the GBL acted as a barrier to divers, who found it difficult to penetrate. The black mud on the top of the salt bed was also observed by the Cambridge Expedition[4] in 1924 and in 1966–67 by El-Sharkawy[8].

It seems likely that as soon as the exchange between the canal and the adjacent seas returns to its normal magnitude, the brine layer will disappear and the salinity at all depths will decrease. I estimate that there will be a sharp drop in the salinity of the brine layer in the first few years followed by a gradual slow decrease afterwards. This assumption is based on the fact that after opening the Suez Canal in 1869 the average annual decrease of the salinity of the GBL was 0.36‰ in the period from 1872 to 1898, became 0.27‰ from 1898 to 1924 and then 0.13‰ from 1924 to 1966 (ref. 8). Although there is no record of the rate of decrease of the salinity in the period from June 1869, during the filling process when the salinity was 168.8‰, to 1872, this rate can be approximately estimated. Taking the salinity in 1966 as 46‰ and the salinity decrease in the period from 1872 through 1966 as 21.84‰, it follows that the salinity in 1872 was of the order of 67.8‰. This means that the annual decrease of salinity in the first two years after opening the canal might have been very sharp.

I strongly suggest that a thorough investigation of the physical, chemical and biological characteristics of the Bitter Lakes and Suez Canal could be made during the present transitional period.

Confinement of thermonuclear microexplosions in imploding vortices

PRESENT efforts towards laser induced fusion envision spherical pellets consisting of the thermonuclear material in the centre, surrounded by a shell of some inert pusher material and an outer ablator shell. The same principles for the pellet design can be used if the implosion process is induced by a relativistic electron beam or intense ion beam (ref. 1, papers presented to Fifth IAEA Conference, Tokyo, 1974 and J. W. Shearer, unpublished). At least one other design of a non-spherical fuel pellet has been published[2]. This is non-symmetric and would have the advantage of using just one laser beam for target bombardment. But in all of these designs there remains one principal difficulty: laser, electron or ion beams with a sufficiently large total energy output for high density pellet compression and efficient thermonuclear burn have a comparatively long pulse length. Therefore, in order to use these beams for the required high density pellet compression rather large aspect ratios $r/\Delta r$ (r=pellet radius, Δr=thickness of pusher and ablator material) are dictated. These may result in rapidly growing Taylor-type instabilities. The growth rate for these instabilities could in principle be reduced below dangerous levels by making the pellet and implosion process highly symmetrical. But, since the symmetry requirements are extreme this may be difficult to achieve. The growth rate for the Taylor instabilities could also be reduced by smaller aspect ratios, but smaller aspect ratios need shorter and precisely shaped pulses, which again are difficult to achieve.

I propose here an alternative pellet design which assures Taylor-stable implosion at high aspect ratios. Figure 1 shows the new pellet design in two cross sections. The pellet has the form of a circular cylinder with cylindrical liners of spiral shape embedded in the pusher and ablator material. The arrows indicate the beams radially and axially bombarding the pellet. In addition to the radial beams, two axial beams are required to compress the thermonuclear material within the pellet axially. The presence of the spiral liners, which are made of some heavy inert material, results in an azimuthal velocity component for the ablated material. If the liners have the form of logarithmic spirals, the ratio of the radial to the azimuthal ablation velocity is constant during the ablation process. As a result of the radial ablation the pellet material is imploded. But the implosion process is here governed not only by the conservation of radial linear momentum but also by the conservation of angular momentum. This results in a collapsing vortex similar to a tornado funnel. The azimuthal motion in the collapsing vortex will give rise to two effects. First, it will stop

Fig. 1 The new pellet design. *a*, Plan; *b*, elevation.
the collapse at a minimum radius of the vortex core at the moment the centrifugal forces become equal to the implosion stagnation force; second, the rapid rise of the centrifugal force during the collapse will make the implosion process Taylor-stable (as in the case of the formation of a tornado funnel). The ratio of collapse (r_0/r_1, where r_0 is the initial radius of the vortex core and r_1 its final minimum radius) can be predetermined by a proper choice of ratio $v_r^{(0)}/v_\varphi^{(0)}$ for the initial ratio of the radial to the azimuthal implosion velocity and thus the slope of the liner spirals. At maximum collapse $v_r = v_r^{(1)} = 0$ and $v_\varphi = v_\varphi^{(1)}$.

Conservation of energy and angular momentum then require that

$$(v_\varphi^{(1)})^2 = (v_r^{(0)})^2 + (v_\varphi^{(0)})^2 \qquad (1)$$

$$r_1 v_\varphi^{(1)} = r_0 v_\varphi^{(0)} \qquad (2)$$

From this one obtains

$$v_r^{(0)}/v_\varphi^{(0)} = [(r_0/r_1)^2 - 1]^{1/2} \simeq r_0/r_1, \quad r_0 \gg r_1 \qquad (3)$$

If one assumes a tenfold compression in radius this yields $v_r^{(0)}/v_\varphi^{(0)} \simeq 10$.

An inertial force directed towards decreasing density results in a Taylor-unstable situation and one directed towards increasing density results in Taylor-stable fluid flow. For the case in question the inertial force resulting from the radial deceleration

$$a_1 \simeq (v_r^{(0)})^2/r_0 \qquad (4)$$

is destabilising, whereas the centrifugal force resulting from the acceleration

$$a_2 \simeq (v_\varphi^{(1)})^2/r_1 \qquad (5)$$

is stabilising. Stability is guaranteed if $a_2/a_1 \gg 1$. From equations (2) and (3) this condition leads to

$$a_2/a_1 \simeq r_0/r_1 \gg 1 \qquad (6)$$

which in my chosen example, $r_0/r_1 = 10$, is well satisfied.

The proposed scheme of a collapsing vortex may be used also for the stable confinement of a microexplosion induced by a high density gas-embedded pinch. Because of the longer time scale involved in such a case, the ablator material may be made out of high explosive material which is radially detonated, eliminating the need for laser or other intense beams to affect the ablation-induced implosion and compression.

Formation of blisters in molybdenum bombarded with helium

THE formation of surface blisters on metals bombarded with low energy inert gas ions was first observed by Primak[1] but only recently, when the potential importance of blistering in the first wall of a fusion reactor became recognised, has much further attention been paid to the phenomenon[2,3]. Most of this work has used scanning electron microscopy to examine the blistered surface although considerable information has also been obtained from gas release measurements both during bombardment and in post-bombardment anneals. Transmission electron microscopy has been used to a lesser extent but nevertheless has yielded important information on the substructure within the layer where the gas atoms came to rest—normally some hundreds of Ångstroms from the metal surface. For example, several workers have shown that gas bubbles form in thin foils irradiated with low energy (<300 keV) helium or argon ions[4–6]. One interesting fact (D. J. Mazey, unpublished) is that over a wide temperature range from 600 °C down to 20 °C, 36 keV helium bombardment of molybdenum produces a fine distribution of helium bubbles crystallising on to a body-centred-cubic (b.c.c.) lattice analogous to the void lattice[4,7]. Here I describe an extension of transmission microscopy to view the blisters themselves and suggest some details of the blister formation mechanism.

Molybdenum samples were irradiated at room temperature with 5×10^{17} 18-keV helium ions per cm^2, these ions having a projected range of approximately 630 Å. Following bombardment the samples were electropolished using a backthinning technique to protect the front damaged surface so that this surface was contained in the final electron-transparent thin section. Both a Philips EM 300 100 keV electron microscope and the Harwell AEI High Voltage Microscope were used for specimen examination. On either microscope the presence of the blisters (Fig. 1),
Fig. 1 800-keV electron micrograph of blisters in helium-bombarded molybdenum. The blisters have diameters between 1 and 1.5 µm.

was made very obvious by the bend contours associated with their dome-shaped profile. The contour patterns seem to be a good example of the type used by Steeds *et al.*[8] for real space crystallography; it was simple to index each contour and use the poles (Fig. 2) to measure the blister radius of curvature. On a finer scale the damage structure consisted of a high density of dislocations—thus making the bend contours considerably less sharp than in a perfect crystal—and a very high concentration of small helium bubbles, radius 15–20 Å. These bubbles were in both the unblistered areas and the blister covers.

McCracken[9] has briefly outlined the process of blister formation as the coalescence of small helium bubbles to form a large high pressure bubble sufficient to deform the surface. This seems to be consistent with the experimental
Fig. 2 A more detailed micrograph of blister bend contours with the main poles indexed.

observations but any detailed mechanism besides describing the formation of the blisters from the small bubbles must also explain at least two important results in the blistering work:

(1) Both scanning electron microscopy and gas release results have demonstrated that a relatively sharp threshold dose exists for blister formation.

(2) At high temperatures the bombarded surface displays a 'pinhole' structure rather than blisters[5,10].

The possible mechanism suggested here is based on the assumption that the coalescence of growing bubbles (at temperatures below that at which bubbles can thermally migrate) only becomes rapid when the bubbles are essentially touching—in other words when the volume swelling due to the bubbles reaches a critical value. In the case of the bubbles being on a perfect b.c.c. lattice, it is easy to show that the volume swelling ($\Delta V/V$) would be 68% but in the random array the situation is a little less certain. But if we proceed on this basis, the reason for the existence of a critical dose is evident and is governed by the maximum volume swelling that can be supported in the peak of the helium stopping distribution. The interesting point is that because the threshold condition is a volume one, then coalescence without any decrease in volume—the likely situation unless the bubble can quickly acquire excess interstitials—will not relieve the tendency for further coalescence. So, on this model the coalescence, once started, becomes a runaway process. From the point of view of blistering the important thing is that the coalescence of two gas bubbles at constant volume must increase the excess internal pressure. For example, if we take two equal equilibrium gas bubbles, radius r, then the internal pressure, p, is given by $p = 2\gamma/r$ where γ is the surface energy. On coalescing, the new equilibrium gas pressure will be lower by a factor of $2^{\frac{1}{3}}$, giving the bubble an excess internal pressure 26% above the equilibrium. As further coalescence takes place, this value will rapidly increase until enough excess pressure is built up to deform the metal surface and create a blister. For the small gas bubbles observed, the equilibrium gas pressures are in the region of 10^4 atmospheres.

At high temperatures the availability of thermal vacancies becomes important[11] between 0.4 and $0.5T_m$. It is therefore possible to define a temperature where the coalesced bubbles immediately collect enough vacancies to relieve their excess internal pressure and regain equilibrium. In this way, not enough pressure can build up to deform the metal surface and blisters will not be formed. Instead the bubbles grow until they cut the surface thus producing the observed 'pinhole' effect.

One important prediction of this model is that in the fusion reactor first wall, which will have a spectrum of ion energies, the integrated dose necessary to build up the critical helium concentrations at any particular depth will be far greater than those found experimentally with mono-energetic beams. Such results would overestimate predicted first wall surface erosion rates and thus the detrimental effects of blistering could be less than anticipated.

A novel method for the calculation of energies of activation for gas reactions

A GENERAL method for the rapid, accurate calculation of activation energies for gas reactions would clearly be of great value. To date, full *ab initio* quantum mechanical calculations of reaction coordinates and potential energy surfaces have been carried out for only the simplest systems and extensions to larger ones are still some way off[1]. On the other hand, semi-empirical approaches[2] which could perhaps deal with larger species require a good deal of accessory experimental information.

We suggest here a simple new approach, based on self-consistent molecular orbital calculations of the Pople–Segal–Santry type[3,4]. This leads first to the heat of activation, $\Delta H^{\ddagger}$ for a reaction and through this to a value for the energy of activation ($\Delta E^{\ddagger}$).

The use of the 'bond index' has been derived and illustrated previously[5,6]. This quantity stems from the density matrix which is, in turn, readily obtainable from a self-consistent field molecular calculation. It is found, for example, that, in the case of CH_4, the C–H bond index is 0.987, and the C–C bond indices in the series C_2H_6, C_2H_4, C_2H_2 are 1.023, 2.032, 2.989. These indices clearly correspond to the chemist's concept of a 'single' bond or a 'double' bond and, on this basis, we suggest that the bond indices can be used, together with experimental heats of atomisation in the standard state, to generate an improved set of standard energy terms for a variety of bonds. These will then allow prediction of the heats of formation for molecules containing them. A particular improvement over the present bond energy concept is that the bond index reflects slight changes in intrinsic bond strength with the environment of the bond in question, further details of which will be published elsewhere (P.G.P.). But an important extension arises because bond indices can be calculated for any system, and can thus

afford, in principle, the heat of atomisation for that system in the standard state.

So the method should be applicable to a species undergoing reaction. By constructing a grid of points on a surface each corresponding to a particular geometry we can follow a reaction path over a saddle. Because of the way in which the bond energy terms are initially defined, we thus obtain the heat of activation, $\Delta H\ddagger$, in the standard state. Calculation of the energy of activation, $\Delta E\ddagger$, follows in a standard way[7].

We here apply the technique to two related hydrogen-transfer reactions, namely, hydrogen abstraction from methane by the methyl and the trifluoromethyl radical,

$$
\begin{array}{ccc}
CH_3\cdot & & \nearrow CH_4 \\
+ \ CH_4 & & \\
CF_3\cdot & & \searrow CF_3H
\end{array}
\quad + \ CH_3\cdot
$$
We assumed that all positions on the reaction coordinate have C_{3v} symmetry, thus,

$$ -\overset{\diagup}{\underset{\diagdown}{C}} - H - \overset{\diagup}{\underset{\diagdown}{C}} - $$
We further assumed that, in the reaction between methyl and methane, the starting and resultant methyl radicals undergo linear changes in the planar $\longleftrightarrow$ pyramidal angles. The $CF_3\cdot$ radical was assumed pyramidal throughout. At the starting point the reactants were separated by 0.5 nm. An energy search was carried out around the transition state in each case and the reaction coordinates were constructed. The activation energies, corrected for specific heat changes on formation of the transition

Stereochemistry of some steranes from geological sources

THE steranes present in crude oils and sedimentary rocks are believed to be derived from the sterols of ancient organisms. Their precise structure and stereochemistry may give important clues about the nature of the original biological materials and about the geochemical processes which they have undergone. Examination of synthetic steranes[1,2] has led us to question the adequacy of reported[3-6] identifications, using only gas–liquid chromatography (GC) and mass spectroscopy (MS), of steranes such as 5α-cholestane, 5α-ergostane, and 5α-stigmastane (=5α-sitostane) in geological samples. The last two, in particular, seem incompletely identified, since the configuration at C-24 has been ignored (although it is of phylogenetic importance in modern organisms[7,8]), and since we find that epimers at C-24, that is II and III, IV and V, are indistinguishable using GC and MS. The use of the names 5α-ergostane and 5α-stigmastane in geochemical work both for steranes of undetermined configuration at C-24 and for synthetic samples of defined configuration is confusing. In the absence of clear IUPAC/IUB rules, we have adopted the names shown in Fig. 1.

The structure and absolute stereochemistry of many steranes can, however, be defined[1,2]; after isolation, by the additional use of optical rotatory dispersion (ORD) and high-resolution (100 or 220 MHz) proton magnetic resonance (PMR) spectroscopy. Preliminary results on the application of these methods to steranes from two crude oils and from Green River Shale are reported here.

A crude oil of unknown age from Rozel Point, Utah[9], was distilled, chromatographed on silicic acid and alumina, and treated with urea to give a sterane-rich fraction. Examination using GC and MS revealed a large number of C_nH_{2n-6} ($n = 26$–30) components with sterane-type fragmentation patterns.

Further separation was achieved by thiourea adduction and preparative GC. A component having the retention time of 5α-cholestane was recrystallised from propanol and confirmed as 5α-cholestane (I) by melting point (80–80.5 °C), mixed melting point, MS, PMR, and ORD. A second recrystallised isolate (melting point 80.5–81 °C), indistinguishable from 5α-ergostane using GC and MS, was revealed as a 1:1 mixture of 5α-campestane (II) and 5α-ergostane (III) using PMR and ORD. These two steranes were separated on alumina (2.8 m × 5 mm column eluted with pentane; method to be published) and the identity of each was confirmed using PMR spectroscopy. The presence in the thiourea adduct of (24R)- and (24S)-4α, 24-dimethyl-5α-cholestanes in a similar ratio was also demonstrated. A component having the GC and MS properties of 5α-stigmastane was isolated from the thiourea non-adducted material and examined without recrystallisation; PMR analysis indicated a 1:1 mixture of 5α-stigmastane (IV) and 5α-poriferastane (V), consistent with the ORD spectrum.

Similar fractionation of a crude oil of Upper Miocene origin from Huntington Beach, California[10,11] also yielded a 1:1 mixture of the epimers II and III. By contrast, the corresponding fraction isolated from a sample of Green River Shale (Eocene) from the Rifle Mine, Colorado, proved to be a 25:75 mixture of epimers II and III, together with a small quantity of an unidentified third component, whereas the major C_{28}-sterane fraction proved to be a 30:70 mixture of IV and V. Although comparisons between data from different samples of the vast
Fig. 1 Structural formulae of steranes isolated from geological sources. I: R = R′ = H; 5α-cholestane. II: R = methyl group; R′ = H; 5α-campestane (24R). III: R = H; R′ = methyl group; 5α-ergostane (24S). IV: R = ethyl group; R′ = H; 5α-stigmastane (24R). V: R = H; R′ = ethyl group; 5α-poriferastane (24S)

Green River Shale formation require caution, our result for the C_{28}-sterane is compatible with the published ^{13}C nuclear magnetic resonance spectrum[12] of Green River Shale "5α-ergostane", which shows deviations from the reference spectrum in the regions (161 and 174 p.p.m. from CS_2) where we find 5α-campestane (II) to differ from 5α-ergostane (III). This is consistent with the presence of a significant proportion of II in that sample.

At least two stereoisomers of 5α-cholestane are present in oil from Rozel Point. (20S)-5α-cholestane (VI) was isolated from the thiourea non-adduct and identified by comparison (GC, MS, PMR, ORD) with an authentic sample[2]; its concentration in the crude oil seems to be comparable with that of 5α-cholestane. A minor C-27 component of the thiourea adduct, homogeneous by GC analysis on several stationary phases, had the retention time of 5α,14β-cholestane (VIII), (ref. 2) and a similar mass spectrum, although the optical activity was considerably lower than expected. The PMR spectrum was interpreted as that of a 40:60 mixture of VII and an isomer in which the 18-CH_3 and 21-CH_3 signals are shifted upfield (δ 1.05 and 0.865, respectively, in C_6D_6). A possible structure for the latter is (20S)-5α,14β-cholestane, and the synthesis of a reference sample is in hand.

Although investigation of these geological samples is incomplete (for example, the identified steranes account for <20% weight for weight of all sterane-like hydrocarbons in Rozel Point crude oil), several interesting points are raised. The preponderance in Green River Shale of one epimer of each of the 24-alkyl-5α-cholestanes suggests that in relatively mild conditions of diagenesis the stereochemistry of precursor sterols is at least partly preserved in the hydrocarbon products; similarly, pristane from this source largely retains the stereochemistry of its putative precursor[13]. The predominant (24S)

stereochemistry may, in addition, point to possible source organisms such as algae[8,14]. The phylogenetic significance of the stereochemistry at C-24 requires further study, however, especially as it is now known that some higher plants produce 24-methylsterols of both (R) and (S) configuration (Mulheirn, L. J., unpublished). Our results also suggest that equilibration at C-20 and C-24 may prove characteristic of petroleum steranes, reflecting the more severe conditions required for petroleum formation. No stereochemical analyses of phytane or pristane from crude oils have been reported, although it may be relevant that farnesane from New Ulm (Texas) crude exhibits complete randomisation of stereochemistry at its two centres of asymmetry (J. W. Cornforth and J. R. Maxwell, personal communication). The occurrence of minor amounts of a 14β-sterane in Rozel Point oil may also be attributed to an equilibration process, the scanty available evidence[15] suggesting that this configuration is the less stable. No natural sterols with a 14β-hydrogen are known.

Finally, the data demonstrate for the first time that the isolated steranes possess the same absolute stereochemistry as that of the corresponding hydrocarbons synthesised from the sterols of modern organisms. No optical rotations have previously been reported for individual steranes from geological samples.

We thank Professor J. W. Cornforth for initiating this work; Drs A. Hood and P. R. Mommessin (Shell Development Company, Houston, Texas) for arranging the supply of the oils and shale; our colleagues at Shell Research Ltd, Thornton Research Centre, Cheshire for preliminary processing of the oils; and Mrs D. Davis, Mrs P. R. Jennings and Mrs S. A. Terry for technical assistance.

Influence of interannual climatic fluctuations on biological systems

GROWTH of conifers in western North America and the distribution of albacore tuna (*Thunnus alalunga*) along the west coast of North America are linked by large scale atmospheric flow patterns which are influenced by air–sea interaction processes over the eastern North Pacific Although the systems respond to their respective environments during different times of the year there is strong evidence that they are reacting to the same climatic fluctuations.

Ring widths of conifers from a variety of semi-arid sites in western North America reflect climatic variations. The spatial anomaly patterns of tree growth have been related to large scale anomaly patterns of the general atmospheric circulation which, in turn, are related to anomaly patterns

of sea-surface temperature (see, for example, refs 1 and 2).

Seasonal migrations of albacore tuna into and out of the coastal North American fishery and the population distribution along the coast are related to changes in the thermal structure of the eastern North Pacific which, in turn, are related to air–sea interaction events[3].

Although it would be desirable to know the yearly variations in the distribution of albacore abundance or the exact number of individuals in the population, the best source of available data is landing statistics compiled for various regions along the North American coast (J. A. Renner, personal communication). These data indicate albacore availability, or accessibility to the efforts of a fishery. A complex situation probably exists where fluctuations in landings result both from environmental influences affecting albacore migration routes (causing yearly variations in their geographical distribution along the coast) and from weather conditions affecting the location and success of the fishermen and/or the behaviour of the fish once they are distributed.

As an indicator of variations in albacore population distribution, the landings reported north of San Francisco were expressed as a percentage of those reported along the entire coast. This assumes the fishing effort is spread along the entire coast throughout each fishing season. Although a complete effort analysis has not been made, boats were operating consistently along the entire coast throughout the analysis period.

To determine whether spatial patterns of tree growth

from 49 sites in western North America and albacore distribution both respond to the same variations in the ocean-atmosphere system, the large scale components of the ring-width variance were transformed into uncorrelated variables (amplitudes of principal component eigenvectors) and then put in stepwise regression to find which of these amplitudes were significant predictors (at the 95% confidence level) of albacore catch. This procedure gave the equation:

$$Y = 35.12 + 5.76A_2 + 5.13A_8 + 8.56A'_4 - 6.17A'_9 + 11.54A'_{10} \quad (1)$$

where Y is the estimated percentage of albacore caught north of San Francisco, A and A' are eigenvector amplitudes corresponding to the catch year and the following year, respectively, and subscripts refer to the eigenvector number (Fig. 1). The regression accounted for 83% of the catch data variance in the calibration period (Fig. 2). The values of tree-growth eigenvector amplitudes for 1700 to 1938 were then substituted into equation (1) to estimate what the yearly albacore catch distribution would have been for this early period based on the patterns of tree growth (Fig. 3).

Although fishery statistics are available after 1961, tree-growth data for all 49 sites within the spatial network are not, and the only independent data available to check the validity of the reconstruction are incomplete fishery catch statistics between 1904 and 1937 (ref. 4). A qualitative comparison between both sets of data shows these common

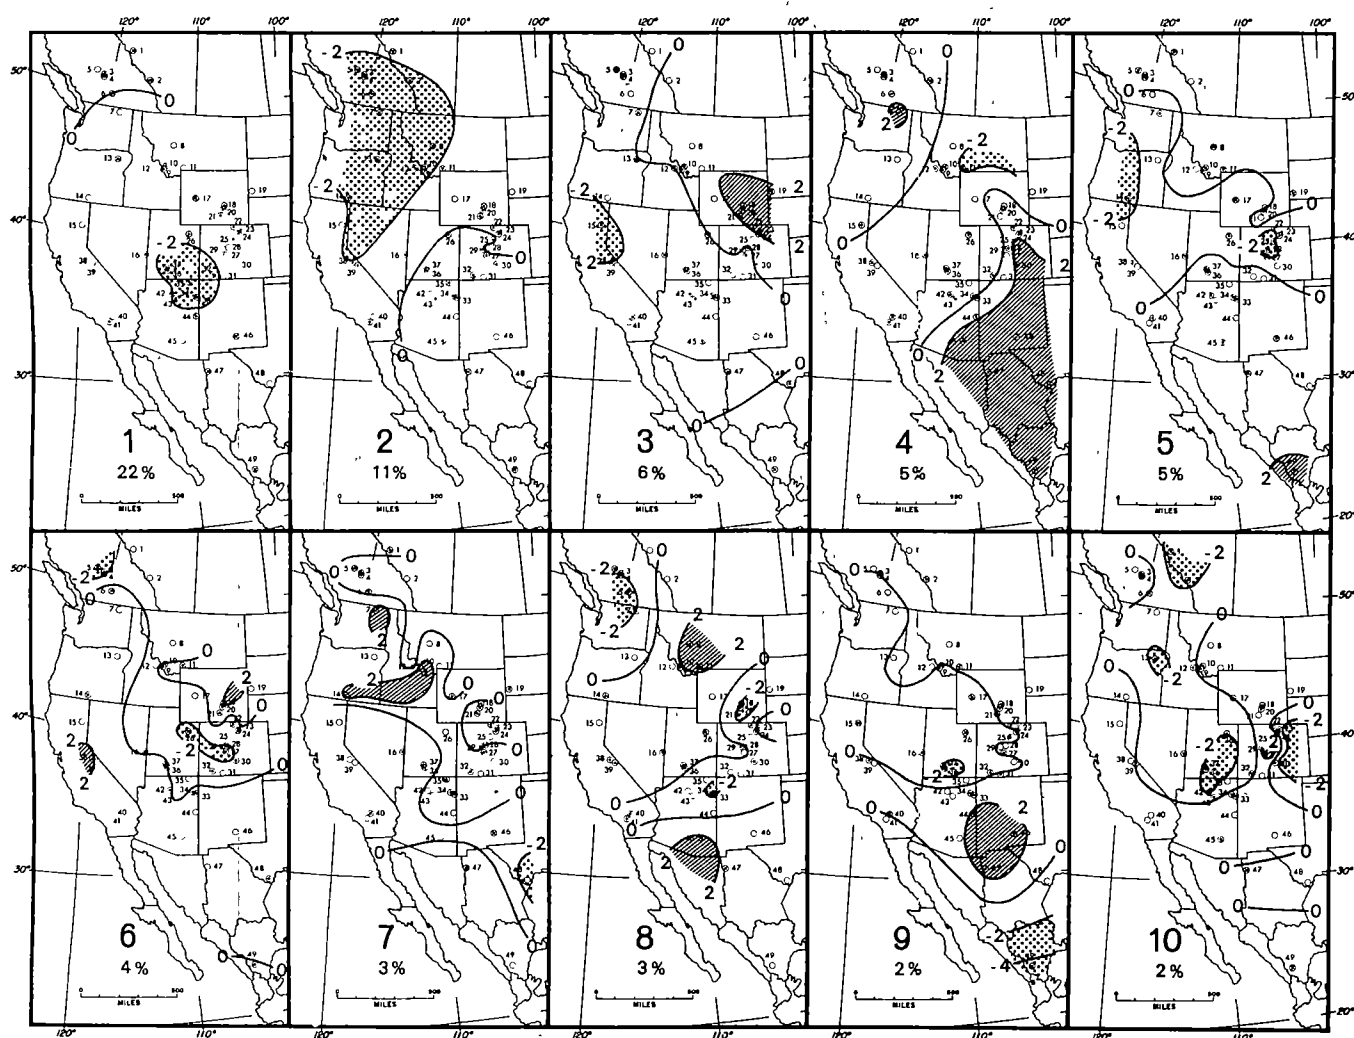
Fig. 1 Maps of the first 10 eigenvectors of ring-width index. The percentage figures refer to the variance accounted for by the corresponding eigenvector. Numbered circles indicate ring-width chronology sites.


Fig. 2 Percentage of the total North American west coast albacore tuna catch taken north of San Francisco, estimated from landings data (———) and percentage catch taken north of San Francisco derived from the calibration equation applied to tree-growth data over the dependent data period (- - - - -). Calibration included the following steps: (1) We computed the 49 by 49 correlation matrix which expressed the interrelationships among the 49 ring-width index series for the period of analysis (1700–1962). (2) The eigenvectors of the correlation matrix were then computed. These (orthogonal) eigenvectors may be expressed in map form as characteristic spatial anomaly patterns of tree growth. The 10 eigenvector patterns which accounted for the most variance (the large scale variance) were selected for further analysis. Maps of these eigenvectors are shown in Fig. 1. Linear combinations of these 10 eigenvectors can reproduce 64% of the ring-width variance for the 49 chronologies during the period of analysis. (3) Each of the first 10 eigenvectors was multiplied by the normalised tree-growth data at each site for each year from 1700 to 1962. The resulting matrix product consists of 10 time series of amplitudes which give the relative importance of each of the first 10 eigenvector patterns (the large scale patterns) in each year's tree-growth anomaly map. Being orthogonal to (uncorrelated with) each other they are easy to use as predictor variables in multiple regression. (4) Since trees respond to the climate of both the concurrent season and previous seasons, a prediction model was constructed including the 10 amplitudes corresponding to the same year as the catch data and the 10 amplitudes corresponding to the year following the catch data, for a total of 20 possible predictor variables. (5) Stepwise multiple regression was used to find those amplitudes that were significant predictors (95% confidence level) of albacore catch distribution for the years 1938–61.
Fig. 3 Percentage of the total albacore tuna catch taken north of San Francisco, estimated from the calibration equation applied to tree-growth data for 1700 to 1961. Shading indicates calibration period.

characteristics· a fishery that was centred off southern California in the early 1900s; a sharp decrease in the availability of albacore to the southern fishery between 1917 and 1918; another decrease in availability of albacore to the southern fishery in 1923 when the total catch was the lowest since 1918; and a prolonged period of decreased availability to the southern fishing fleet after 1928. The reconstructed distribution data indicate that a fishery would have been centred quite far north after 1929 and through the late 1930s if boats had operated there during that period. The absence of albacore from the catch record for Oregon and Washington before 1937 and low catches for California after 1925 probably reflect the extreme northward and offshore population distribution indicated by the reconstructed data; the fish were just not available to salmon trollers that did operate close to shore north of California during this period[5].

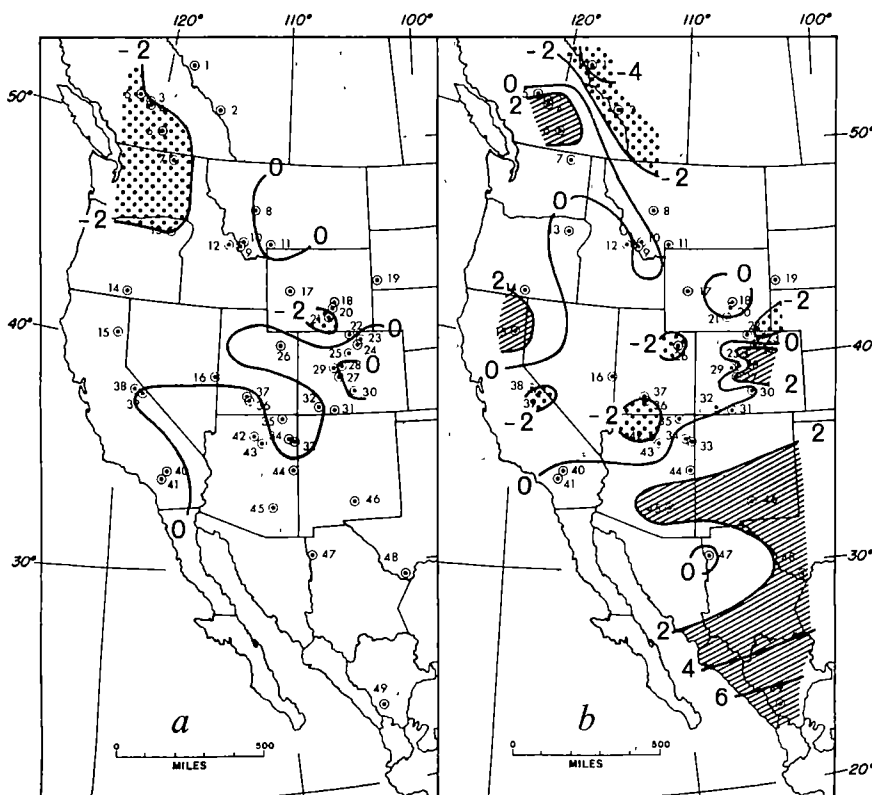
We also examined the eigenvector patterns of tree growth that were chosen by regression to be associated with a high percentage of albacore caught north of San Francisco. The tree-growth pattern corresponding to the year of the catch


Fig. 4 Tree-growth anomaly patterns associated with above normal percentages of albacore caught north of San Francisco. Map *a*, corresponding to the year of the catch, is formed from the linear combination of eigenvectors 2 and 8 in equation (2); map *b*, corresponding to the year following the catch, is formed from the linear combination of eigenvectors 4, 9, and 10 in equation (3).

can be represented by a map composed of eigenvectors 2 and 8 as follows:

$$\text{map } a = 5.76 \text{ (eigenvector 2)} + 5.13 \text{ (eigenvector 8)} \qquad (2)$$

where the numerical coefficients are taken from equation (1). Similarly, the tree-growth anomaly pattern corresponding to the year following a high percentage of albacore caught north of San Francisco can be represented as:

$$\text{map } b = 8.56 \text{ (eigenvector 4)} - 6.17 \text{ (eigenvector 9)}$$
$$+ 11.54 \text{ eigenvector 10)} \qquad (3)$$

These maps are presented in Fig. 4. The ring-width data were mostly from trees sited in arid localities, so that a wide ring would generally be associated with anomalously cool, cloudy weather and above normal precipitation whereas a narrow ring would reflect warm, sunny and dry conditions.

Below, normal tree growth in the Pacific North-west (Fig. 4) is indicative of dry conditions associated with below normal cyclonic activity during the fishing season. Sunny and mild weather would favour albacore fishing in adjacent waters, as would above normal insolation regardless of weather. The resulting excess of stored heat in the ocean would be given up through evaporation during the following autumn and winter and lead to increased cyclonic activity and precipitation along the coast north of San Francisco. These conditions would lead to increased tree growth during the following growing season (Fig. 4).

Autumn and winter climatic anomaly features, combined with spring climate and the year-to-year autocorrelation of tree-ring widths, produce the other ring-width anomaly features in Fig. 4 for the following growing season. Narrow ring widths south of San Francisco, for example, imply below normal precipitation—an expected feature since winter precipitation in the Pacific North-west is negatively correlated with winter precipitation in southern California[6].

The reconstructed values of albacore catch distribution data (Fig. 3) and inferred population distribution also seem to exhibit long term changes over intervals of 100 yr or more, which suggest the possibility that long term fluctuations in the ocean–atmosphere system may be involved.

The success of the calibration of tree rings with albacore catch indicates the possibility of relating tree-ring variations to any type of biological variations which are affected by large scale climatic fluctuations. Such relationships may be quantified and used to reconstruct objectively other climatically-caused biotic variations in the past.

Oats may grow better in water depleted in oxygen 18 and deuterium

WHILE growing oats at different temperatures in water of different ^{18}O and deuterium (D) abundances, we noticed that oats grown in Antarctic water in which is depleted in ^{18}O and D by $-49‰$ and $-400‰$, relative to standard mean ocean water (SMOW used as a comparative reference in hydrogen and oxygen isotope studies), showed initial growth 1–2 weeks sooner than did oats grown in water containing greater ^{18}O and D concentrations. The oats seemed to grow better in water which was most depleted in the stable isotopes throughout the growth period.

The oats were grown from the same batch of seeds in two sealed glass-covered glass jars (approximately 10 l). Twenty-five oat seeds were added to each jar, containing the same amount of vermiculite and 500 ml water to which 5.0 g Rapid-Gro, a commercial fertiliser, had been added. One jar contained melted glacial ice from the Antarctic with isotope concentrations of $-49‰$ $\delta^{18}O$ (SMOW) and $-400‰$ δD (SMOW). The other jar contained distilled ocean water with $+1.0‰$ $\delta^{18}O$ (SMOW) and $+17‰$ δD (SMOW). Both jars were placed in the chamber at the same time.

The experiment was repeated three times with new materials: once the growth chamber was maintained between 1.7 and 3.3 °C; once between 24 and 26.6 °C; and once the temperature fluctuated between 1.7 and 26.6 °C. Each time the oats in the jar containing water depleted in the heavy isotopes showed germination 1–2 weeks earlier and seemed to grow better throughout the growth period, than oats grown in distilled ocean water.

Using oats grown at 15 °C, the first sign of germination in the jar containing water depleted in the heavy isotopes was 4 d after planting. On the day 6, eight plants (out of 25) had attained a height of 6 cm. The first sign of germination in the jar with water containing the heavier isotope concentration, was after 17 d. By the time five plants had attained a height of 6 cm in this jar, in that with water depleted in the isotopes, 23 plants that had reached the top of the jar (approximately 25 cm).

Kashutin[1] observed that snow-water depleted in D increases the yield of cucumbers, radishes and spring wheat compared with controls grown in ordinary water of unspecified isotopic composition. He cites experiments on the egg productivity of hens and the weight gain of suckling pigs. In both cases water depleted in D was especially efficient in promoting productivity.

Although much has been done on the effect of D-enriched water on biological systems, we suggest that research on the effect D-depleted water on plant and animal growth may prove fruitful. A major source of water depleted in D by over 400‰ (40%) compared with SMOW is snow and ice from the Antarctic polar plateau. Water depleted by 150–180‰ is readily available in the USA from Rocky Mountain snow precipitating above 10,000 feet elevation.

Identification of chlorinated dibenzofurans in American polychlorinated biphenyls

MORTALITY of embryos has contributed to the reproductive failures of several bird species, including the sparrowhawks (*Accipiter nisus*) of southern Scotland[1], the white-tailed eagles (*Haliaeetus albicilla*) of Schleswig Holstein[2], and the herring

gulls (*Larus argentatus*) of Lake Ontario[3]. Suspected causes include p,p'-DDE (2,2-*bis*-(p-chlorophenyl)-1,1-dichloroethylene), other chlorinated biocides and/or their derivatives, and the polychlorinated biphenyls (PCBs), all of which are present as contaminants in the eggs[1-3]. PCBs are present in high concentrations in the bird populations which suffer embryonic mortality[1-3]. Other organochlorine compounds which may be present in food webs include the chlorinated dibenzodioxins and the chlorinated dibenzofurans (Fig. 1), which are toxic to embryos in amounts[4-7] less than 1 μg. They are therefore among the most toxic substances known and are possible causes of the observed mortality.

The chlorinated dibenzodioxins and chlorinated dibenzofurans, however, have proved exceedingly difficult to detect in environmental samples in the concentrations at which they are expected to be embryotoxic[8-10]. The chlorinated dibenzodioxins enter the environment as contaminants in preparations of the herbicide 2,4,5-T (refs 5 and 11) and the fungicide pentachlorophenol[12,13]. Chlorinated dibenzofurans have been found in a French (Phenoclor DP6) and a German (Clophen A60) PCB and were shown to be the active embryotoxic agent in these preparations[6]. The techniques used, however, did not detect chlorinated dibenzofurans in an American PCB, Aroclor 1260. We report here the presence of chlorinated dibenzofurans in Aroclor PCB, widely used in North America and Great Britain, and in the same Aroclor 1260 preparation examined previously with negative findings[6].

Samples of PCB examined include: Aroclor 1248, 1254, and 1260 (1969); Aroclor 1254 (1970); Aroclor 1016 (1972); and the same three preparations studied by Vos et al.[6]: Aroclor 1260, lot No. AK-3; Clophen A-60, lot No. 912434; and Phenoclor DP-6, lot not specified. The latter three PCBs were obtained from Dr Vos, the others from the Monsanto Company in the years indicated in parentheses.

PCBs extracted from environmental samples most often have gas chromatographic profiles similar to those of PCB formulations containing approximately 48, 54 or 60% chlorine. In the Aroclor series, the former two PCBs are equivalent to Aroclor 1248 and Aroclor 1254, respectively. Aroclor 1260, Phenoclor DP6, and Clophen A60 all contain approximately 60% chlorine.

Chlorinated dibenzofurans were identified in all Aroclor preparations except Aroclor 1016, as well as in Clophen A60 and Phenoclor DP6. Aroclor 1016 is a PCB mixture containing
Table 1 Chlorinated dibenzofuran concentrations* in Aroclor, Clophen and Phenoclor

PCB	4-Cl	5-Cl	6-Cl	Total
Aroclor 1248 (1969)	0.5 (25)	1.2 (60)	0.3 (15)	2 0

*Expressed as μg g^{-1} PCB. Values in parentheses represent quantity as percentage total dibenzofuran.
ND, not detected (< 0.001 μg g^{-1}).

Amounts of PCB ranging from 1.0 to 2.0 g were dissolved in 400 ml hexane, placed on a Florisil column (180 g, internal diameter 31.5 mm), and eluted with: an additional 1,600 ml hexane, and successive 800 ml volumes each of 5% diethyl-ether–hexane, 25% diethyl-ether–hexane and acetone, at a rate of approximately 7 ml min^{-1}. The major portion of the PCB was eluted in the hexane fraction, which was discarded. On addition of the 5% mixture, the eluates were collected in six successive 400 ml volumes. To eliminate the polar solvents, each eluate was evaporated twice just to dryness and taken up each time in a minimal amount of hexane Each fraction, in 1 ml hexane, was placed on a microalumina column[14] and eluted with 10 ml each of 1% and 20% methylene chloride in hexane. These were also taken twice just to dryness and made to up a volume of 1 ml in hexane to eliminate the methylene chloride before gas chromatographic analysis. Aliquots of all fractions obtained before and after partitioning on alumina were injected into a six foot glass column containing 3% OV1 on 100–120 mesh Supelcoport in Tracor MT220 and Hewlett–Packard 5700 gas chromatographs equipped with ^{63}Ni electron-capture detectors. PCBs were found to be present in each fraction eluted from the Florisil column in amounts sufficient to interfere with the detection of trace contaminants. Partitioning on the alumina columns separated most of the PCB interference into the 1% methylene chloride fractions. On removal of this interference, different peak patterns appeared in the chromatograms of the 20% methylene chloride fractions. Compounds eluting in the 20% methylene chloride fraction were collected for mass spectrometric analysis using a 20:1 effluent splitter, and a trap consisting of a capillary tube (1 mm internal diameter, 100 mm long) bent to a U shape, immersed in a liquid nitrogen bath. Methylene chloride (20%; 4 μl) in hexane was injected into the capillary as a rinse, removed with a 1.0 μl micropipette, and placed directly on the mass spectrometer probe. The probe was inserted into a GEC AEI MS902 high resolution mass spectrometer and the solvent removed by the force pump. The probe was rapidly inserted into the ion source and multiple scans were recorded in the on-line high resolution mode[15].

Fig. 1 Skeletal structures of: *a*, chlorinated biphenyl, $x+y = 1$–10; *b*, chlorinated dibenzofurans, $x+y = 1$–8; *c*, chlorinated dibenzodioxins, $x+y = 1$–8.

approximately 42% chlorine and has replaced Aroclor 1242 in many applications, principally as the dielectric fluid in capacitors[16]. Values reported in Table 1 represent the total of those compounds found in 400 ml Florisil fractions 2–6. A total of 10–12 isomers was identified in each PCB. Two chlorinated dibenzofuran contaminants have been reported for the Clophen and Phenoclor previously[6]; our first analyses of the Clophen revealed an additional five chlorinated dibenzofurans[8]. The structures contained four to six chlorine atoms. Other dibenzofurans including those chlorinated to a lesser extent may have been present in the first 400 ml fraction but this was not examined in detail as it contained substantial PCB interference. Recently synthesised 2,3,7,8-tetra-, 2,3,4,7,8-penta- and 2,3,4,6,7,8-hexachlorodibenzofuran were used to quantify tetra-, penta-, and hexachlorodibenzofurans, respectively. The former two authentic standards had retention times on the OV1 column the same as those of two dibenzofurans isolated from the PCB.

Vos et al.[6] detected no chlorinated dibenzofurans in an Aroclor 1260 preparation at a detection limit of 1 p.p.m. Fractionation and examination of the identical Aroclor 1260 in our study confirm their findings based on the stated limit, but reveal the presence of 11 chlorinated dibenzofurans in the preparation, having a total concentration of 0.8 μg g^{-1} PCB (Table 1). The same workers also found diethyl ether extracts of the Clophen A60 and Phenoclor DP6 to be much more toxic to chick embryos than diethyl ether extracts of Aroclor 1260. Our study confirms those findings on the basis of chlorinated
Fig. 2 *a*, Gas chromatogram of a fraction of Aroclor 1254 containing a mixture of chlorinated biphenyls, dibenzofurans, and naphthalenes Identities of peaks are given in the text. *b*, Mass spectrum of peak 2, a tetrachlorodibenzofuran.

dibenzofuran content: the identical Clophen and Phenoclor contain 11 and 17 times more total chlorinated dibenzofurans, respectively, than the Aroclor 1260.

A gas chromatogram showing components derived from the Aroclor 1254 obtained in 1969 is represented in Fig. 2. The components were eluted in the second 400 ml Florisil fraction and recovered from the alumina column in 20% methylene chloride–hexane. Each of the numbered peaks was trapped as described here, and identified by mass spectrometric analysis. A nominal mass plot of the high resolution mass spectrum of peak 2 is shown in Fig. 2. The plot includes all the ions with elemental compositions ranging to the maximum empirical formula $C_{13}H_6O^{35}Cl_5^{37}Cl_4^{13}C_2$. The molecular ion cluster at nominal m/e 304–310 fragments by successive losses of Cl to yield the ions at m/e 269–275 and CO to the ions at m/e 241–245. A minor loss of Cl from the peaks at m/e 269–275 also occurs to yield the ions at m/e 234–238, followed by CO elimination to m/e 206–210.

The group of peaks at m/e 152–154 are the doubly charged molecular ions. An identical spectrum was obtained from an authentic standard of 2,3,7,8-tetrachlorodibenzofuran. This latter compound has a retention time identical to that of peak 4. Peak 2 is, therefore, a positional isomer. The accurate mass measurements for the characteristic ions are within 2 p.p.m. of the calculated exact masses. Peaks identified on this chromatogram and their retention times relative to dieldrin are as follows: a mixture of tetra- and pentachlorobiphenyl (1.02); tetrachlorodibenzofuran (1.30); pentachlorobiphenyl (1.46); tetrachlorodibenzofuran (1.57); hexachloronaphthalene (1.75); pentachlorobiphenyl (1.86); hexachloronaphthalene (2.00); and heptachloronaphthalene (3.46). An aliquot of combined fractions derived from the same Aroclor 1254 was treated with diazomethane to assess whether any chlorinated ortho-hydroxy-biphenyls (pre-furans) were present. Gas chromatographic analysis of the sample before and after treatment resulted in identical chromatograms.

As large quantities of PCBs have entered the global environment[17-20], it may be assumed that the contaminant dibenzofurans

also have been released in proportional amounts. Their persistence, effects, and significance remain to be determined.

We thank J. A. Burke, M. L. Porter and J. G. Vos for discussions; A. S. Kende for standards of chlorinated dibenzofurans; and F. C. Walls for assistance with the mass spectrometry. This work was supported by the Canadian Wildlife Service, National Science Foundation, and NASA.

Niche breadth in Bryozoa as a test of competition theory

COMPETITION theory predicts that intraspecific and interspecific competition should often have opposite effects on the use of resources by a population, the former increasing, the latter decreasing, the range of resource actually used[1,2]. Field data supporting these predictions are well known for the interspecific case[3,4] but are scarce for the intraspecific condition, and we have been unable to find any reference demonstrating both effects within a single species. We therefore report here the verification of both predictions in respect of competition for space by the epiphytic bryozoan *Alcyonidium hirsutum;* less extensive data suggesting the same effects within other bryozoans are also reported.

Intraspecific competition should result in an increase in the range of a resource spectrum used by a species, as 'at high population levels the advantages to any individual of being at the competition-free optimum of a resource gradient are offset by the intense intraspecific competition found there (Fig. 1a); this is the 'principle of equal opportunity' of MacArthur[1]. Interspecific competition, on the other hand, should tend to restrict the range of the resource spectrum used by a species, as individuals attempting to exploit marginal resources cannot do so as efficiently as

individuals of other species for which these resources are more nearly optimal; niche width on the resource gradient is thus reduced. Furthermore, such reduction can be expected to increase with increase in the number of competing species, as a greater proportion of the original resources is then nearer the optimum for a competing species (Fig. 1b); this is the diffuse competition situation of MacArthur[1,2]. These predictions will have been confirmed if it can be shown that the range of a resource spectrum used by a species increases with population density but decreases as the number of competing species increases.

Our analysis is based on the distributions of Bryozoa on plants of the serrated wrack *Fucus serratus*. Sixty-five plants were collected in April, 1972 near Ardkeen, County Down, Northern Ireland, and the longest frond of each divided into Y-shaped dichotomies, labelled Y1, Y2, and so on, from holdfast to tip. The percentage cover by each bryozoan species was recorded for each of the two faces of each dichotomy. The commonest bryozoans were *Alcyonidium hirsutum, Electra pilosa, Flustrellidra hispida* and *Membranipora membranacea;* other bryozoan species were sufficiently rare to be ignored in this analysis. Fuller details of our methods have been recorded elsewhere[5].

Fig. 1 Niche breadth changes under the influence of intraspecific (a) and interspecific (b) competition. In a, high density (HD) curve is broader than is the low density (LD) curve as more individuals settle at more marginal but less hotly contested points on the resource gradient. In b, presence of competitors utilising resources on both sides of a species' optimum on the resource gradient compresses that species' niche breadth.
In an epiphytic community of filter-feeders such as that found on *F. serratus*, competition for space is of major significance: each fucoid frond constitutes a linear resource which can be partitioned longitudinally among the competing species[5,6]. We therefore tested MacArthur's principle of equal opportunity by plotting the longitudinal range of *Alcyonidium* on each plant against its population density on that plant, using only the fourteen plants on which it was the sole bryozoan present and thus eliminating the effects of interspecific competition from other bryozoans. The results (Fig. 2) show that *Alcyonidium* used a greater range of Y values (height when the plants are upright, as an index of distance from the holdfast) at high population densities than at low densities. As the available space at the optimum height was not physically filled as populations increased this must result from competitive interactions between colonies[7], thus confirming the prediction of increased range of resource use. Note that
Fig. 2 Niche breadth in relation to population level for *Alcyonidium* in the absence of competition from other bryozoa. Niche breadth estimated as the range in Y value of colonised segments, calculated separately for each side of a frond and averaged. Population level is estimated as the mean percentage cover of all colonised segment faces of the plant. O, Anomalous result discussed in text. Regression is significant ($r = 0.631, P < 0.05$).

one plant gave anomalous results because of extremely distal settlement of a very few zooids (Fig. 2); the regression is statistically significant when this point is included ($r=0.631$, $P<0.05$) but on omitting it the correlation rises to 0.890 ($P<0.01$), thus almost doubling the proportion of variance in resource span accounted for by population density.

Too few plants were colonised by another single bryozoan species to allow precisely the same analysis as for *Alcyonidium*. For these other species we therefore included plants on which any one other bryozoan was present even though this introduced some interspecific competition tending to reduce niche breadths (see below) and thus to mask the intraspecific effect. Nevertheless, for each species a positive correlation between range and density per plant (on a log scale) was obtained (*Electra, r*=0.595, *P*<0.025; *Flustrellidra, r*=0.363, *P*<0.30; *Membranipora, r*=0.606, *P*<0.09), thus suggesting a niche widening effect for intraspecific competition in these species also.

It is in principle possible for the results above to have arisen through a pattern of age-dependent settlement by Bryozoa on growing *Fucus* fronds[5]. We therefore examined

Fig. 3 Resource utilisation curves for *Alcyonidium* with different numbers of competing Bryozoa present. Ordinate, number of *Fucus* segment faces colonised; abscissa, Y value. ●—●, Faces colonised by *Alcyonidium* alone; □—□, faces colonised by *Alcyonidium* and any one other bryozoan species; ●...●, faces colonised by *Alcyonidium* and two other bryozoans.
Table 1 Effect of interspecific competition on niche breadth in Bryozoa

Number of competing species present	Alcyonidium		Electra		Flustrellidra		Membranipora	
	Breadth	Cases	Breadth	Cases	Breadth	Cases	Breadth	Cases
0	5.9	149	5.1	59	6.8	51	5.0	41
1	4.4	69	2 6	58	6.1	57	1.7	18
2	2.7	18	1.6	20	1.6	20	1.0	2

Niche breadth was assessed from plots such as those of Fig. 3 as the width of the resource utilisation function at half-height. Cases column shows the sample size on which each function was based. The second and third rows are based on all cases satisfying the row criterion, irrespective of the identity of the competitor(s).

the distribution of each species on each plant in the light of the age of that plant as indexed by the number of dichotomies on the longest frond: no systematic pattern was apparent in any case, thus precluding that explanation.

The effects of interspecific competition on *Alcyonidium* niche breadth were examined by plotting the distribution of segment faces colonised by *Alcyonidium* with (in turn) no other, one other and two other bryozoan species on the same face. The results (Fig. 3) show that *Alcyonidium* used a wider range of heights on the plants in the absence of competition than in its presence, and used a wider range when competing with one species at a time than with two. These results are summarised with those for the other three species in Table 1, using the width at half-height of each resource utilisation function as an index of niche breadth; the standard deviations used for this purpose by MacArthur[1] were not appropriate with the non-Gaussian distribution found here[8]. Table 1 shows that niche breadth was reduced progressively in all four species as the number of competing species increased, thus confirming the theoretical prediction for the effects of interspecific competition. Note that these results did not arise as artefacts of partial overlapping of largely segregated resource utilisation functions[5].

A number of previous studies, particularly those demonstrating ecological release in island populations of birds[3,4], have shown interspecific competition to restrict niche breadth. The effect of intraspecific competition in increasing niche breadth has been less well documented, although it can be inferred from the 'buffer effect' of population studies, in which marginal habitats are utilised by territorial animals only at high population levels[9]. These two types of study have rarely been combined to contrast the effects of interspecific and intraspecific competition within a single species, probably because of the practical difficulties of assessing population density and resource use simultaneously. The more rigorous test of competition theory reported here was possible because of the special features of the group studied, bryozoans on *Fucus* competing along what is effectively a single resource dimension on which their densities are readily assessed. A detailed account of habitat partitioning in bryozoans will be published elsewhere.

Hue is an absolute code for young children

THE question of how young children see, remember, and learn represents a recurring theme in psychology. Bryant[1] has argued provocatively that "young children can on the whole register and remember relative values with great ease, but have problems in situations in which they must remember absolute values along any continuum". Bryant shows[1] how this view of early cognitive functioning accounts for the results from studies of children's responses to several environmental continua of a perceptual nature (for example, orientation, size, and position). I have, however, observed that young infants respond to changes of wavelength in a manner which indicates that they code hue absolutely.

Bryant has reanalysed extant studies and described new data which show that children perform well at simultaneous discrimination tasks (where comparison stimuli are available at the same time as a standard) whereas they perform poorly at successive discrimination tasks (where choice stimuli are available after a standard has been withdrawn). On the basis of this evidence, Bryant proposed that children use relative codes to make simultaneous comparisons. Successful performance in successive comparisons requires a constant external framework or an absolute code of stimulus characteristics; in general, Bryant has found that where mediating environmental features were wanting children's performances at successive discriminations fell to chance. Relative codes rather than absolute codes, he concluded, are therefore primary in young children, and the growing reliance on absolute codes, if it occurs at all, is a late developmental phenomenon. In this view, man's initial perception and memory of environmental stimuli are dominated and controlled exclusively by their relationships to each other or to surrounding frames of reference.

Contrary to Bryant's analysis, for a stimulus dimension (wavelength) which conforms to his investigative requirements (both absolute values of stimuli and relationships among stimuli can be specified) and in an experimental situation (successive discrimination) which fits his physical requirements (luminous figures were presented without a frame of reference in an otherwise dark room), infants in my studies were observed to use absolute codes in successive discrimination. That is, infants responded to hues on an absolute basis with no alternatives other than those which may be inferred to be internal categories of information. This is much the way that adults respond to hue[2-3].

Ten infants (mean age, 124 d) were first familiarised with a 480 nm stimulus: they were shown a light—which appears to the adult mostly 'blue' with some 'green'— serially for 15 trials each of 15 s duration. During this

familiarisation phase (and during the test phase which followed) the infants' observation of the light was monitored by observers unaware of the stimulus wavelength (judgment reliabilities: 0.93< r <0.97), and the total observation times per trial were later scored blindly from event records. Typically, familiarisation to one stimulus leads to shorter periods of observation on successive presentations of that stimulus; after familiarisation, continued exposure to the original stimulus or to a different stimulus coded as the same as the first leads to a continued depressed level of looking, whereas exposure to a different stimulus coded differently from the first leads to increased visual attention[4]. Immediately following the familiarisation phase, infants experienced nine test trials (each of 15 s duration) in which they saw 450 nm, 480 nm, and 510 nm stimuli serially in three different random orders. Thus, in the test phase, infants saw the familiarisation stimulus (480 nm or 'greenish-blue') and two new stimuli: 450 nm or 'blue' and 510 nm or 'green'. Adults see and code 450 nm and 480 nm as similar and as drawn from the same basic hue category, but they see and code 480 nm and 510 nm as different and as drawn from different basic hue categories. This experiment (Table 1) showed that infants looked at 450 nm and 480 nm for an equal and relatively little amount of time but that they looked at 510 nm for significantly longer ($F=16.77$, $P<0.001$, by a planned comparisons analysis[5]).

In a successive discrimination task in a situation lacking external frames of reference, infants responded to equal extents to a wavelength with which they had been previously familiarised and to another from the same basic hue category, which they had not seen previously; but they responded to a greater extent than that to a wavelength which they had not seen previously and which was drawn from a different hue category. Internal controls showed that differential responses could not be a function of fluctuation in attention (the familiarisation stimulus appeared randomly during the test) or simple change in wavelength (the two new stimuli were equally distant in wavelength from the familiarisation stimulus). Moreover, in a similar successive discrimination task, infants who were familiarised with a luminous oblique line did not discriminate it from its mirror image; that is, they gave equal amounts of attention to both. It is clear from this pattern of results that infants can code wavelength absolutely by apparent hue and can respond to changes in wavelength with respect to a set of basic absolute hue codes, whereas they cannot code orientation absolutely[1].

It is an explicit claim of Bryant's theory that young children, possessing exclusively relative codes, should be able to perform successive discrimination tasks and concomitant perceptual inferences only in the presence of a constant frame of reference. Without such a reference, absolute codes are necessary, and lacking such codes children perform at chance. The possession by infants of an absolute code for hue (and for certain speech sounds[6]) represents, however, a case which Bryant happily provided for: "Abilities which have been definitively ruled out in young children by one psychologist have a habit of cropping up in the experiments of another". The presence of hue codes in young infants helps us further understand the

nature of early sensory and perceptual processes and of the demonstrative predominance of colour over form in young children's natural classification systems[7].

Sexual transfer of specific genes without gametic fusion

THE most common method of combining genes from two organisms is by sexual hybridisation. In plant breeding, however, a variety can often be improved considerably by introducing only one or a small number of specific genes. Elimination of accompanying undesirable characteristics normally requires several generations of backcrossing and selection which may greatly prolong the breeding period. Here I describe experimental results which suggest a possible new technique for more rapid transfer of desired genes between two organisms.

During experiments on the role of 'mentor pollen' in overcoming intraspecific incompatibility in *Nicotiana*, some unexpected observations were made. In some cases, as expected the use of 'killed' irradiated (100,000 rad, Co : 347.6 rad min^{-1}) mentor pollen mixed with the viable maternal incompatible pollen led to the breakdown in the self incompatibility system resulting in the production of selfed progeny. (Mentor pollen is compatible irradiated pollen which produces a growth tube but fails to fertilise the ovule. In certain genotypic combinations substances are released by the mentor pollen which allow normally incompatible pollen to produce a growth tube able to fertilise the ovule.) In other cases the mentor pollen had no effect and usually no seed was produced. But in these latter combinations, which involved the related but morphologically distinct intercompatible species *N. forgetiana* and *N. alata*, in a few cases rare viable seeds were produced along with a large number of collapsed non-viable ovules.

These seeds gave rise to 24 normal, fertile, diploid plants which, in general morphological characteristics, all resembled their maternal parents. Surprisingly, however, most of these plants showed coloured flowers and/or an incompatibility allele characteristic of the mentor pollen source (Table 1). Fourteen of the 24 plants were examined cytologically and all were found to be normal. No additional chromosome fragments[1-3] were present.

To investigate this apparent 'gene transfer' phenomenon, 14 plants showing flower colour and/or an S allele typical of the mentor pollen source were crossed with various tester plants of known genotypes (Tables 2 and 3). The most significant result of these test crosses was the recovery of 34 plants carrying 3 S alleles from crosses C2-1, C2-2, C2-3, D6-1 and D7-1 (Table 3). Triallelic plants of this type cannot be obtained by any normal form of inheritance and their appearance is strong evidence for the occurrence of an unusual genetic transfer process

A number of other anomalous features of these experimental results also suggest the transfer of genes from irradiated mentor pollen without normal gamete fusion :
(1) Although the exceptional plants may have been derived from rare pollen nuclei which survived the irradiation

*Families were derived from single pods except for (B) which was derived from two pods with two seeds in each. Normally a pod contains up to 1,000 or more seeds.

†Only 14 of the 24 plants were examined cytologically.

‡To overcome the problem of breakdown of incompatibility reaction in parthenogenetic diploids when tested with highly heterozygous testers[5], only appropriately inbred plants were used as *S* gene testers in these experiments.

treatment, the extremely high lethal dose of 100,000 rad has a margin of error which virtually rules out this possibility. In addition, any plant arising from fertilisation by an irradiated nucleus would be expected to show extreme sterility, lack of vigour, or gross morphological defects. No such effects were observed.

(2) In families A and B (Table 1) where the mentor pollen was obtained from a different species, the progeny were unequivocally maternal in floral and general morphology, and were definitely distinct from normal F_1 *N. forgetiana* × *N. alata* hybrids.

(3) In the same families, A and B, in which the mentor pollen parent was homozygous for the S_3 gene, the progeny were all homozygous for one or other maternal *S* allele, whereas if they arose through normal fertilisation by mentor pollen they would all have carried the S_3 allele, And yet the participation of the mentor pollen parent is unequivocal, for the red flower colour of the progeny could have come only from that parent.

(4) Also in families A and B, nine out of the 11 progeny were red-flowered, whereas according to the genotypes of the parents a true hybridisation should have given a ratio of 1 red to 1 white.

(5) Contamination with foreign pollen cannot explain the anomalous plants in Table 1. First, the plants were all grown in an insect-proof greenhouse and experimental procedures were strictly controlled. Second, contamination would be expected to produce extremely rare pods with a full set of viable seeds, but in these crosses the pods were too frequent and the number of viable seeds per pod too low to represent accidental contamination.

(6) Although the anomalous plants from crosses A to D are highly fertile (60–9$\tilde{?}$% stainable pollen), some nevertheless show a greater degree of pollen sterility than is usually observed in normal cross-pollinated plants of this genus.

(7) Finally, a unique phenotypic abnormality was recovered among the progeny of four anomalous plants, C1, C2, C4 and D4. In these plants, which are otherwise normal in appearance, the 'floral' shoot became vegetative with tufts of small leaves in place of flower buds. When these plants were cut back to the stem base they regenerated the original

type of vegetative inflorescence. No such plants have previously been seen or reported in *Nicotiana*[4] to the author's knowledge. This novel phenotype was apparently generated as a consequence of unorthodox genetic recombination processes.

*Testers were normal diploid plants, homozygous recessive for flower colour (rr). In B4-4 a heterozygous red-flowered tester (Rr) was used. Brackets indicate reciprocal crosses.

†Segregation expected if the transferred gene is heterozygous and behaves normally. 1:1 segregations. Crosses A2-3 and B4-3 show significant excesses of red-flowered progeny ($P < 0.05$). Overall there is a highly significant excess of red-flowered progeny ($P < 0.01$). 3:1 segregations. Individual segregations are not significantly different from expectation, but the overall data show a highly significant excess of red-flowered progeny ($P < 0.01$).

‡Includes normal and 'transferred' red flowered plants.

The following sequence of events is proposed as a working hypothesis to explain the above results.

The extremely high dose of irradiation given to the mentor pollen 'pulverises' the generative nucleus to produce a mass of fine chromatin fragments. Division of the generative nucleus fails, and this may contribute further to chromatin fragmentation. Discharge of the pulverised chromatin from the pollen tube into the egg acts as a 'pseudo-fertilisation'. The block to cell division in the egg is lifted as usual and the chromosomes are replicated, but the presence of disorganised pollen chromatin prevents a normal first zygotic division. This results in a diploid egg with the 'induced' physiology of a zygote. Presumably, at least in certain cells, the free chromatin fragments are rapidly degraded, or lost, and their disorganising effects are soon overcome to enable subsequent mitotic divisions to occur normally. The resulting embryo will be a parthenogenetic diploid. Rare occurrence of parthenogenetic diploidy after pollination with irradiated pollen has previously been reported in *Nicotiana*[5]. The slightly greater pollen sterility shown by some of the anomalous plants is mainly attributed to parthenogenetic diploidy exposing deleterious recessive genes.

Fragments of mentor pollen chromatin may occasionally associate with their homologues among the egg chromatin. These fragments will have broken 'sticky' ends and may insert into nicks formed during chromosome replication[6]. The following possibility is suggested to explain why the pollen chromatin fragments should be attracted to the homologous segments in the egg chromatin in a manner reminiscent of meiotic pairing. Once replication has been induced, the homologous pollen chromatin molecules are

able to compete successfully with the *de novo* synthesised molecules, since they occupy the respective positions next to the strand before the appropriate molecules could be freshly synthesised.

Once chromatin segments from pollen have paired with those of the egg, substitution or addition may easily occur during replication. Three types of chromatin transfer can be imagined (Fig. 1a, b, c). It is interesting to note that results consistent with these patterns of transfer have actually been found (Table 3) Plant D6 illustrates the triallelic state (Fig 1b), and plant C2 probably illustrates the alternative triallelic state (Fig. 1c). Plants C2 and D7—the third plant showing the triallelic state—illustrates the instability of the exosome, producing three types of gametes (Fig 1e). The remainder of tested plants in Table 3 represent the substituted state (Fig. 1a).

The gene transfers observed in this study seem to be fairly stable. No variegated or blotchy flower coloration, characteristic of *Petunia* transformations[7], was obtained. Only in certain rare cases are there noteworthy deviations from expected segregation ratios (Table 3). As regards flower colour, however, there may be a general tendency to recover an excess of coloured flowered plants bearing the transferred gene. This apparent selection in favour of the transferred gene is not related to the direction of the cross, thus ruling out any advantage in terms of pollen tube growth.

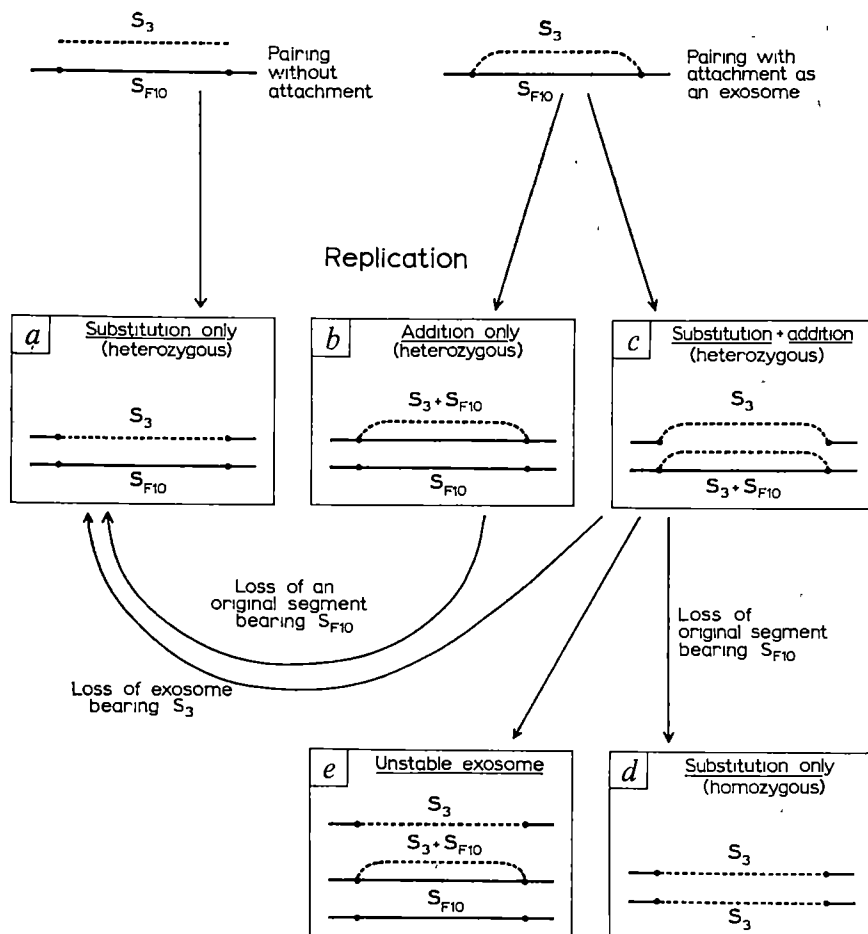
Previous 'transformation' studies[7-10] with higher organisms have so far been unable to distinguish unequivocally between substitution and addition models of chromatin transfer. In the present results, since the presence or absence of individual *S* alleles in the style can be determined


Fig. 1 Diagrammatic illustration of proposed patterns of gene transfer. Genetic states corresponding to *a*, *b*, *c* and *e* have been observed experimentally (see text). —————— Egg chromatin strand (or replicated copy). ------------- Irradiated pollen chromatin (or replicated copy). Single lines represent strands of 'chromatin', not single strands of DNA.

*Testers were normal diploid plants with white (pp) or pink (Pp) flowers. Brackets indicate reciprocal crosses.
†These are white flowered plants with no apparent 'transferred' flower colour factors.
‡Segregation expected if the transferred gene is heterozygous and behaves normally.
§Includes normal and 'transferred' red flowered plants.
¶Plant C2(S_1S_{F11}) apparently forms (S_1S_{F11}) as well as (S_1) and (S_{F11}) gametes and viability of different types of gametes vary between combinations.
‖Plant D6(S_3S_{F11}) apparently forms gametes (S_{F11}) and (S_3S_{F11}) only.
**Plant D7(S_1S_{F10}) apparently forms (S_1S_{F10}) as well as (S_1) and (S_{F10}) gametes.
††Highly significant excess of pink-flowered plants ($P < 0.01$). All other '1:1' segregations do not differ significantly from expectation but are homogeneous in direction. The overall data show a highly significant excess of pink-flowered progeny ($P < 0.01$).
‡‡Highly significant deficit of pink-flowered plants ($P < 0.01$). All other '3:1' segregations do not differ significantly from expectation.
§§One class carrying transferred S gene. Cross C1-1 shows a significant deficit of the transferred gene ($P < 0.05$). Cross D5-1 shows a highly significant excess of the transferred gene ($P < 0.01$). Other segregations do not differ significantly from expectation.
¶¶Both classes carrying the transferred S gene. Cross D1-3 shows a significant excess of the S_3S_{F11} combination. All other segregations do not differ significantly from expectation.
‖‖Contained certain number of abnormal plants with vegetative floral shoots ($C_{1/3}$—5 plants, $C_{2/2}$—8, $C_{2/4}$—2, $C_{4/2}$—2, $D_{4/1}$—3).

it has been possible to demonstrate that both substitution and addition have occurred, although substitution seems to be predominant. It should be noted, however, that the patterns of transfer seen in these experiments may not be strictly comparable with those seen in previous attempts to induce transformation in higher organisms with chemically extracted preparations of DNA and chromatin. Extraction procedures and consequent denaturation of chromatin[11] are avoided by the present method, and the exogenous chromatin is received by a single specialised type of cell.

There are certain important features of the present results for which there seems to be no reasonable explanation at present. The frequency of specific transfers of the flower colour and S genes (the only two genes investigated) is unaccountably high among the rare seeds produced. One might suggest that there is a selection for the S gene transfer, for the heterozygosity of the S complex which is involved in the physiology of reproduction may be instrumental in the induction of parthenogenetic diploidy. The same cannot be said to be true of the flower colour gene however. There is a lack of S gene transfers in families A and B (Table 1) compared with families C and D. The segregation data, particularly of plants C1, C2, D1, D5 and D7, suggest the existence of situations which may influence gametic selection in extreme and contradictory ways. Apparently, wide variability is inherent in this induced phenomenon.

Doy *et al.*[12] have coined the term 'transgenosis' to describe the "transfer of genetic information from one cell to

another followed by phenotypic expression". The present phenomenon in *Nicotiana* can be regarded as a specialised from of 'sexual transgenosis'. Although there are certain mysterious aspects of the gene transfer phenomenon observed in these experiments, these new techniques are theoretically and technically attractive.

I thank Mr R. J. Trott, Palmerston North Hospital, for his help in the irradiation of pollen and Mr G. B. Petterson for technical assistance.

Salt-dependent bacteriophage infecting *Halobacterium cutirubrum* and *H. halobium*

MOST molecular genetic mechanisms are sensitive to ionic strength. The isolation of phage for *Halobacterium* allows a study of genetic adaptation in the extremes of ionic strength. The usual requirement for low ion concentrations is reversed in *Halobacterium* which maintains intracellular KCl near saturation[1]. As a result, macromolecular structure may be altered sufficiently to favour genetic mechanisms that occur rarely or not at all in other organisms. The presence of a unique DNA density distribution[2] and RNA-dependent RNA-polymerase[3] in *Halobacterium* suggests that such alterations occur.

Specific ion requirements define, to a great extent, the ecological niche of halophilic species, providing an advantage in general studies of phage ecology. The nature of halophilic genetic adaptation has a bearing on the suitability of seawater evaporates as sites for biogenesis and evolution.

Halobacterium flourishes in salt saturated environments and requires 10–12% NaCl to remain viable[4]. Water samples bearing phage were collected from The Salt Ponds of Yallahs, Jamaica, where the salt concentration varies from about 10% to saturation, depending on rainfall. Enrichment cultures were prepared from 1 ml of crude sample incubated in halophile broth for five d at 37 °C with aeration followed by addition of 2 ml late stationary phase *H. cutirubrum* and 10 d of additional incubation. The resulting culture was shaken with 1 ml chloroform and the supernatant collected after low speed centrifugation. Phages were purified by picking isolated plaques several times in succession from plates showing only a single plaque with *H. cutirubrum* as indicator.

Only phages forming clear plaques were detected in enrichment cultures or by direct plating of a sample containing 20% salt collected when the halobacterial flora was returning after having been greatly reduced by rainwater. One of these was selected and designated Halophage Ja. 1. The host range of phage Ja. 1 includes strains of *H. cutirubrum* and *H. halobium* reported in Table 1. The frequency of colonies surviving high multiplicities of phage varies widely among sensitive strains and several resistant colonies showed altered pigmentation. A mixed population of phages forming clear and turbid plaques on *H. cutirubrum* was present in a second sample collected 5 months later after evaporation had resulted in salt saturation and a red halobacterial bloom.

For determination of nucleic acid content lysates of Ja. 1 were purified by differential centrifugation and filtration through Whatman No. 1 filters. Concentrated suspensions were dialysed into 0.2 M NaCl, 0.05 M MgSO₄, 0.01 M Tris (*p*H 7.4) before a final cycle of low and high speed centrifugation. This procedure removes nucleic acid adhering to heavy cell debris while phage viability is maintained. Purified suspensions containing 10^{12} phage per ml were dialysed into 0.1 M NaCl, producing an extremely viscous clear solution of disrupted phage and $<10^4$ viable phage per ml. Reaction of the disrupted phage with diphenylamine[5] showed 1.5×10^8D DNA are present for each viable unit before disruption. This amount of DNA slightly exceeds the estimated capacity of the phage head shown in Fig. 1. Further purification of phage Ja. 1 on preformed CsCl gradients gave a single, sharp band of viability at 1.55 g cm⁻³ containing proportionately the same amount of DNA per viable unit. The presence of double-stranded DNA is confirmed by specific immunological assay as is single stranded DNA after boiling for 5 min. Double
Fig. 1 Halophage Ja.1 suspensions in 0.2 M NaCl, 0.05 M MgSO₄ were fixed on Formvar–carbon-coated grids in glutaraldehyde vapours for 10 s and negatively stained with uranyl acetate. The bar represents a distance of 0.1 μm. The phages pictured here are of the same morphological group although larger than particles observed in crude preparations of *H. salinarium* flagella[11].

stranded RNA, RNA–DNA hybrids and single stranded DNA before heat treatment are not detected with corresponding antisera (refs 6 and 7 and A.C.W. and B.D.S., unpublished).
